Common cause models (see Figure 19.1a–d) include diverse theories and levels of analysis. These models implicate shared vulnerabilities (e.g., genes, traits); common risk factors in many forms, including psychosocial disadvantage; shared mediators (such as parenting and physiological stress); and complex combinations (e.g., risk gradients, diathesis-stressor models). These models also include classical disease models, where one disease process produces two kinds of problems at the same time or sequentially (illustrated in Figure 19.1d). Some models focus on one or two levels of analysis (individual behavior and parenting; cognitive functioning and peer interactions); others focus on many levels (genes, neural function, personality, family functioning, school and neighborhood qualities).

Competence problems and symptoms of psychopathology can be caused by the same disease process manifesting in multiple ways. In some cases (discussed in the next section), this model is assumed to be true (e.g., for Autism and other mental illnesses viewed as neurodevelopmental disorders). In other cases, there may be an unknown disease process leading to what is currently viewed as two or more different disorders. For example, Pine, Cohen, and Cohen (2000) have reported evidence that respiratory regulation might play a role in the development and expression of both childhood anxiety disorders (specifically, Separation Anxiety Disorder and perhaps Generalized Anxiety Disorder of Childhood) and adult Panic Disorder. They have shown that childhood anxiety disorders, in a similar fashion to Panic

Disorder in adults, are associated with carbon dioxide hypersensitivity. In addition, work on comorbidity and relationships among Tourette's syndrome, Obsessive-Compulsive Disorder, and Attention-Deficit/Hyperactivity Disorder (ADHD) has suggested that related brain dysfunction in circuits involving basal-ganglia thalamocortical pathways might explain the high co-occurrence of these nonetheless distinct clinical conditions (Pennington, 2002; Sheppard, Bradshaw, Purcell, & Pantelis, 1999). Such work, though intriguing, remains somewhat speculative and awaits further delineation of relevant neural pathway models in nonclinic samples (Sheppard et al., 1999).

Vulnerability, common underlying disease, and diathesis-stressor models suggest that a common trait or dysfunction in the organism contributes to more than one form of adaptive problem. For example, a twin family study suggested that depressive symptoms and antisocial behavior might have a common genetic liability (O'Connor, McGuire, Reiss, Hetherington, & Plomin, 1998). As another example, individual differences in the capacity to regulate emotion, attention, or behavior could easily contribute to multiple domains of competence (such as peer relations and school performance) and are also found in diagnostic criteria for disorders such as ADHD and on measures of problem behavior. Attention problems, inhibition, impulsivity, and negative emotionality all have been associated with multiple problems and disorders. As a simple example, inhibition to the unfamiliar is a robust individual difference evident early in childhood that predicts anxiety disorder, internalizing symptoms, lower social competence, and delays in taking on new social roles (Caspi, 1998; Caspi & Shiner, in press; Fox, Henderson, Marshall, Nichols, & Ghera, 2005; Gest, 1997; Kagan, 1998). More broadly, Rothbart and Bates (1998) have delineated multiple ways that temperament and adjustment could be related. It is likely that multiple processes, direct and indirect, are involved in the explanation of how particular genes, temperaments, and other individual differences lead to both competence problems and psychopathology.

Other personality traits, such as levels of impulsivity and conscientiousness, predict multiple outcomes, including school success, drug use, conduct problems, some personality disorders, and work problems (Caspi, 1998; Caspi & Shiner, in press; Shiner, 2000). The processes by which a personality trait predicts diverse outcomes such as drug addiction and school failure in the same person may differ. These processes also could differ across individuals, depending on their circumstances: In one case, a child in a neglecting family, poor neighborhood, and bad school may encounter many stressors with few assets, getting into

Figure 19.1 Causal models linking competence and psychopathology. (a) Common cause, with common risk factor; (b) Common risk factor and common vulnerability/moderator; (c) Common mediating cause; (d) Common underlying disease or disorder; (e) Psychopathology influences competence; (f) Competence influences psychopathology; (g) Transactional model, with lagged bidirectional effects; (h) Transactional model, with concurrent bidirectional effects; (i) Cascade or progressive chain of causes. *Notes:* Subscript numerals denote time point of assessment: C = Competence, D = Underlying disease process, M = Mediator, P = Psychopathology, R = Risk factor, V = Vulnerability.

every conceivable form of trouble; in another case, a child may have every advantage and be influenced by well-off, popular peers to try fashionable drugs, which leads to addiction and consequent academic problems.

Lower intellectual ability, as well as difficulties directing and sustaining attention, predict both academic and externalizing problems (Coie & Dodge, 1998; Hinshaw, 1992; Hinshaw & Anderson, 1996; Rothbart & Bates, 1998). Good intellectual and attentional skills have been associated with resilience among children at risk due to psychosocial adversity, as indexed by multiple criteria for adaptation, including competence and psychopathology (Masten & Reed, 2002).

Though there has been considerable interest in the role of individual traits in competence and symptoms, there also has been extensive research on shared contextual or experiential causes of multiple outcomes. Major risk factors—such as parenting, socioeconomic disadvantage, and traumatic life experiences—have been implicated as predictors of many aspects of competence as well as predictors of many disorders and symptom dimensions. Shared risk, therefore, could account for some of the observed co-occurrence of problems in competence and psychopathology, particularly if many risk factors or high cumulative risk has primarily nonspecific effects.

Parenting, for example, has been linked to many symptoms, disorders, and competence problems in normative and high-risk situations (Bornstein, 1995; Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Cummings et al., 2000; Masten & Powell, 2003; Masten & Shaffer, in press; Repetti, Taylor, & Seeman, 2002). Parenting itself has many determinants (Belsky, 1984), and, as a result, parenting can serve as a final common pathway through which psychosocial disadvantage, adversity, or work problems of parents are mediated in the family, to the detriment of child rearing (Grant et al., 2003; Masten & Shaffer, in press). Child maltreatment, often but not always perpetrated by parents, also has been linked to many outcomes, including competence failures and psychopathology (Cicchetti & Carlson, 1989; Masten & Wright, 1998).

Risk factors commonly co-occur, and when they do, poor outcomes appear to be more likely in general, across multiple domains (Masten & Gewirtz, 2005; Masten, Morison, Pellegrini, & Tellegen, 1990; Sameroff, 2000a, 2000b, in press; Sameroff & Chandler, 1975; Sameroff, Gutman, & Peck, 2003; Wright & Masten, 2005). *Risk gradients* reflect the rising likelihood of problems as risk factors aggregate in the life of an individual. There has been considerable interest in identifying the underlying processes that account for these gradients (Keating &

Hertzman, 1999; Rutter, 1979; Sameroff, Seifer, & Bartko, 1997; Sameroff, in press). These may be very diverse, with different processes accounting for effects in different domains. Alternatively, these risks could operate through a common mediator, such as parenting or stress, with broad effects on behavior. It would not be surprising for major dysfunction in key adaptive systems to have broad effects across multiple domains.

The breadth of the domains related to high cumulative risk in many studies suggests that important adaptive systems for human development likely have been compromised, either by damage or by overload (Masten & Coatsworth, 1998; Masten & Curtis, 2000). When cumulative risk is very high, and nonetheless the children are doing well, then there is presumed to be either some kind of protection of these adaptive systems, more capacity available to the child, or resources not assessed by the gradient counteracting the risk. In effect, such children are “off-gradient” in doing better than one would predict based on risk factors alone. Similarly, when children known to be vulnerable encounter the key threat and do not develop the expected problems to which they are vulnerable, protective processes also are assumed to be operating.

Psychopathology Undermines Competence

In contrast to the common cause models, wherein the same underlying cause (whether a disease process, vulnerability, or experience) results independently in symptoms of disorder and also competence problems, the following categories of causal models implicate processes by which either psychopathology leads to competence problems (depicted in simple form in Figure 19.1e), or competence failures lead to psychopathology (depicted in Figure 19.1f), or both. When psychopathology is presumed to undermine competence, then in some way, the causal explanation involves features of the disorder interfering with the capacity or success of adaptive behavior. In the words of Ezpeleta et al. (2001, p. 901), “It is well established that psychiatric disorders result in many psychosocial problems, deviations, and limitations in addition to the ‘symptoms’ that are used to establish the nature of the disorder itself.” In other words, the nature of the psychopathology under consideration produces impairment in key domains of adaptive function.

Adequate mastery of developmental tasks requires the coordinated use of multiple capabilities to direct behavior in context over time. Academic achievement in school-age children requires a child to be able to understand language, pay attention, sit still, concentrate, control the impulse to attack other people or laugh at the teacher, organize work, remem-

ber numbers, words, ideas, or pictures, get along reasonably well with the teacher and classmates, and many other skills and learning tools. Disorders characterized by profound difficulties in directing attention, thinking, learning, or relating to other people, including ADHD, Mental Retardation, Schizophrenia, and Autism, would be expected to interfere with academic progress, and they typically do. Not surprisingly, the *DSM* often describes academic difficulties as key related features of these disorders.

The Pervasive Developmental Disorders, including Autism, are defined by severe, chronic problems in basic cognitive and social dysfunctions that would be expected to interfere with most, if not all, major developmental task domains. Children with Autism have great difficulty making friends, learning in a regular school setting, and later managing all the social and cognitive tasks associated with living on one's own, working, and romantic relationships (Dawson et al., 2002; Travis & Sigman, 2000).

In other cases, where basic cognitive, emotional, or other neuropsychological functions are severely disturbed for a period of time, there may be a deterioration of functioning that tracks the development of the disorder or appears as a clear consequence of disturbed behavior (as noted earlier in the example from Lehman et al., 2002). Individuals experiencing delusional or disorganized thinking or severe disruptions of mood associated with psychosis, for example, may behave in ways that wreak havoc with relationships, make learning impossible, or require confinement, thereby impairing or even destroying the accomplishments and adaptive behavior expected by society.

More subtle disturbances of specific aspects of functioning are also associated with distinct profiles of impairment, although when dysfunction in the individual is less severe or less widespread in nature, it is more likely that the organism can compensate. Children with ADHD often have difficulties in their peer relations as well as their school work, because difficulties with directing attention and controlling impulses can interfere with play as well as learning (Campbell, 2000; Hinshaw, 2002b). Children with Tourette's syndrome or Obsessive-Compulsive Disorder have hallmark symptoms (such as tics or time-consuming rituals) that interfere with classroom performance and peer acceptance (Carter, Pauls, & Leckman, 1995; Peterson, Leckman, & Cohen, 1995). In the case of mood disorders, there may be complex transactional effects (described later in the chapter), but in some cases, the behavior associated with extremely depressed or elated mood clearly influences relationships. A depressed adolescent, for example, may withdraw from all social interactions with friends or become socially unappealing to peers, and a manic youth

may become sexually promiscuous or engage in risky or dangerous behaviors that alienate peers or harm friendships and romantic relationships in other ways (Cicchetti & Toth, 1998; Geller et al., 2000; Puig-Antich et al., 1993).

Broadly defined antisocial behaviors have been clearly associated with changes in competence over time, most particularly academic performance. Antisocial behavior appears to have negative effects on academic achievement, even controlling for the initial links (Bardone, Moffitt, Caspi, Dickson, & Silva, 1996; Chen, Rubin, & Li, 1997; Hawkins, Smith, Hill, Kosterman, & Abbott, 2003; Masten et al., 1995; Risi, Gerhardstein, & Kistner, 2003; Williams & McGee, 1994).

Broadly defined internalizing behaviors are less clearly associated with changes in competence over time, though severe depression and anxiety (meeting diagnostic criteria for Major Depression or anxiety disorders) do forecast future competence problems. For example, adolescents with anxiety disorders or depression have more academic problems currently and in the future compared with nondisordered youth (Bardone et al., 1996; Bernstein & Borchardt, 1991; Kovacs & Devlin, 1998). Yet, there are not many consistent longitudinal data indicating predictive validity for internalizing symptoms in relation to undermining academic or social attainments (Cole, Martin, Powers, & Truglio, 1996; Roeser, Eccles, & Sameroff, 2000). One of the most intriguing linkages of psychopathology symptoms and competence in the literature actually works in the opposite direction.

There is reason to believe that internalizing symptoms may function to reduce the risk for subsequent competence failures among youth with some antisocial behavior, acting as a kind of braking system for the development of rule-breaking conduct problems and associated risky behaviors. Though limited, data suggest that internalizing symptoms have a negative predictive effect with respect to changes in externalizing symptoms, such that youth with more internalizing problems show less increase in externalizing problems over time (Farrington, 1995; Kellam, 1990; Loeber & Keenan, 1994; Mesman, Bongers, & Koot, 2001; Moffitt, Caspi, Harrington, & Milne, 2002; Verhulst, Eussen, Berden, Sanders-Woudstra, & Van Der Ende, 1993). This effect, if further substantiated, might be related to the role of inhibition in development or a protective effect of self-isolating behavior when peers are deviant (Gest, 1997; Kagan, 1998; Moffitt et al., 2002).

In other cases, the pathways by which psychopathology undermines competence may be less direct, with mediating processes. For example, a child with ADHD or conduct problems or both may be removed from a normal classroom

and placed in a special education classroom for behaviorally disturbed children. If this classroom placement leads to either social stigma or association with more deviant peers who reinforce antisocial behavior or less adequate instruction, there may be unintended negative consequences for the child's academic and social competence. In a related fashion, Dishion, McCord, and Poulin (1999) have compellingly described the potential iatrogenic effects of aggregating deviant adolescents in peer-group-based intervention efforts, with evidence of increasing delinquent behavior through "deviancy training" and peer reinforcement of deviant talk, shown at both 1-year (Dishion, Andrews, & Crosby, 1995) and 3-year (Poulin, Dishion, & Burraston, 2001) follow-ups.

Competence Failures Contribute to Psychopathology

Causal models and empirical studies have also implicated the consequences of failures in adaptive achievements expected by self and society in the development of symptoms of psychopathology. There are several major ways that competence problems may contribute to psychopathology: (1) Perceived failure could lead directly to distress and related internalizing symptoms; (2) competence problems could increase the risk of negative experiences with peers, teachers, parents, or others that aggravate or increase symptoms; and (3) competence problems could lead to a change in context (e.g., special classroom placement or school dropout) that alters the nature of opportunities, results in stigmatization, or increases affiliation with negative associates.

Failure models in developmental psychopathology incorporate causal effects of competence failures on the development or exacerbation of symptoms, though some of these models involve complex transactions and cascades discussed further, later in the chapter. Patterson and Capaldi, with colleagues (Capaldi, 1992; Patterson & Capaldi, 1990; Patterson & Stoolmiller, 1991), have proposed one of the classic models of this kind, a "dual failure model" of depression, where failures in social and academic arenas were hypothesized to lead to dysphoric mood. In an influential longitudinal study of conduct problems and depressed mood in adolescence, this team found that conduct problems predicted increasing depressed affect over time, whereas depressed affect did not add significantly to the prediction of changes in conduct problems (Capaldi, 1992). Their developmental model posits that behavior problems arising early in development contribute to competence fail-

ures, which in turn contribute to worsening conduct problems and also worsening mood.

David Cole and colleagues (Cole, Martin, & Powers, 1997; Cole et al., 1996; Jacquez, Cole, & Searle, 2004) also proposed a failure model for depression, in which competence problems contributed to depressed mood. Through path analysis and structural equation modeling (SEM), this group found that social competence predicted changes in depressed affect over time, whereas the reverse was not found. Cole et al. (1997) have suggested that this effect is mediated by perceived competence. Additional work by this research team testing mediating versus moderating influence of self-perceived competence shows additional support for mediation (Jacquez et al., 2004; Tram & Cole, 2000).

With respect to academic achievement, there is evidence consistent with failure effects for both externalizing and internalizing domains of behavior. Though the evidence is more consistent with externalizing symptoms undermining academic attainment in the elementary school years, by secondary school academic achievement problems appear to have negative effects on subsequent conduct, which could result from association with deviant peers, greater exposure to violence, or other intermediary processes (Deater-Deckard, 2001; Dishion, Patterson, Stoolmiller, & Skinner, 1991; Patterson, Forgatch, Yoerger, & Stoolmiller, 1998; Williams & McGee, 1994). It has also been observed that academic achievement during adolescence is associated with desistance from antisocial behavior (Maguin & Loeber, 1996; Thornberry, Lizotte, Krohn, Smith, & Porter, 2003). Academic failure also appears to relate to increases in internalizing symptoms, and achievement gains predict improvements in depressive symptoms, though this evidence is relatively sparse and somewhat less consistent than the evidence linking conduct and academic achievement over time (Chen, Rubin, & Li, 1995; Cole et al., 1997; Kellam, Rebok, Mayer, Ialongo, & Kalodner, 1994; Maughan, Rowe, Loeber, & Stouthamer-Loeber, 2003).

It is also interesting to consider the effects of conduct problems on internalizing behavior, given that conduct problems can be viewed as failure in a major competence domain. In this context, externalizing problems would be taken as evidence of failure in the developmental task of rule-governed behavior. There is some evidence implicating externalizing behavior problems as a predictor of changes in internalizing symptoms, congruent with a failure model (Capaldi, 1992; Garber, Quiggle, Panak, & Dodge, 1991; Kiesner, 2002; Lahey, Loeber, Burke, Rathouz, & McBur-

nett, 2002; Loeber & Keenan, 1994; McGee, Feehan, Williams, & Anderson, 1992; Robins, 1986).

Getting along with peers is widely viewed as a central developmental task by middle childhood; later in middle childhood and throughout adolescence, having a chum (Sullivan, 1953) or friends is also recognized as a hallmark of good development and a harbinger of future competence (Hartup, 1996; Masten, 2005; Masten & Coatsworth, 1998; Roisman et al., 2004). Peer rejection, which can occur for many reasons, some unrelated to already existing psychopathology in the rejected individual (such as discrimination), has been associated with increasing risk for externalizing and internalizing behavior (Deater-Deckard, 2001; Hartup, 1996; Masten, 2005; Parker, Rubin, Price, & DeRosier, 1995; Rubin, Bukowski, & Parker, 1998). Of course, symptoms in a child such as aggression (Ladd & Troop-Gordon, 2003) and anxiety (Gazelle & Ladd, 2003) may contribute to peer rejection, which in turn may contribute to subsequent internalizing and externalizing symptoms. Peer rejection can be viewed as a source of adversity in the form of “relational stressors” (e.g., victimization, exclusion) that contribute to psychological problems (Ladd & Troop-Gordon, 2003).

The practice of tracking children into lower-achieving classrooms due to academic performance or retaining them in grade may increase the risk for subsequent internalizing or externalizing problems (Pagani, Tremblay, Vitaro, Boulerice, & McDuff, 2001; Roeser & Eccles, 2000). Increases in behavior and emotional problems could result from the effects of concentrating deviant children together in a classroom, who may reinforce each other’s negative behaviors (Dishion et al., 1999), or by lowering expectations for academic performance of children, teachers, and parents, or injuring self-esteem (Roeser & Eccles, 2000).

The most powerful tests of these competence failure models would consist of intervention studies to enhance competence in experimental designs and ascertain if preventing failure prevents psychopathology. This evidence is addressed in more detail in the subsequent section on prevention. However, an early example of this strategy is provided by the work of Kellam and colleagues (1994), who hypothesized that a reading intervention in the early primary grades would prevent internalizing symptoms; their results from a classic study in the Baltimore public schools supported this view. Similarly, the long-term effects of early intervention programs to promote academic and social competence in preschoolers on later antisocial behavior and other negative outcomes of interest have been interpreted as evidence that promoting social competence

early in development reduces the risk for antisocial behavior and psychopathology (Ramey & Ramey, 1998; Reynolds & Ou, 2003; Shonkoff & Meisels, 2000; Shonkoff & Phillips, 2000; Zigler, Taussig, & Black, 1992).

It is interesting to note that Model f in Figure 19.1 is usually discussed in terms of competence failure leading to symptoms, but it is also plausible that there is action at the high end of competence. In other words, competence achievement may be reducing psychopathology. In fact, many of the early theories about competence suggest that evolution and societies are selecting for competence, and, as a consequence, it is reasonable to assume that many aspects of competence may be linked to powerful motivation and reward systems and that self-righting systems would be in place to promote positive adaptation. If so, interventions that focus on improving competence may work in part by harnessing some of these powerful adaptive systems (Masten, 2001).

Complex Dynamic Models: Transactional, Progressive, and Cascade Effects

One of the most striking changes evident in developmental psychopathology over the past decade, since the publication of the first edition of this volume, has been the growth of models with a dynamic systems perspective (Cummings et al., 2000; Cicchetti & Davies, 2004; Masten, in press; Sameroff, 2000a, 2000b). Concomitantly, there are more conceptual and empirical models linking competence and psychopathology that include bidirectional influences and progressive effects across domains over time.

The complex, dynamic models owe much of their conceptual perspective to the developmental systems theorists (e.g., Bronfenbrenner, 1979; Cicchetti, 1990b; D. H. Ford & Lerner, 1992; Granic & Hollenstein, 2003; Gunnar & Thelen, 1989; Sameroff, 1983, 2000a, 2000b; Sroufe, 1979; Thelen & Smith, 1998). These models assume that many interactions of organisms and environments give rise to behavior, and that causal effects are often mutual or bidirectional. As a result, competence and psychopathology may be linked by more complex processes over time than implied earlier in the chapter, such that all of the effects described earlier could be occurring at the same time or sequentially. Effects within these more dynamic and complex models are described by terms such as *transactional*, *cascade*, *amplification*, *growth*, and *snowballing*, suggesting more dynamic, complex, and embedded effects in a context of interactions (Cicchetti & Cannon, 1999; Cicchetti & Tucker, 1994; Dodge & Pettit, 2003; Hinshaw

& Anderson, 1996; Masten et al., 2004, in press; Masten & Coatsworth, 1998; Patterson, Reid, & Dishion, 1992; Sameroff, 2000a, 2000b). These effects account for the long-observed diffusion of problems over time, particularly when there are antisocial or academic problems (Dodge & Pettit, 2003; Hinshaw, 1992; Kohlberg, LaCrosse, & Ricks, 1972; Maguin & Loeber, 1996; Masten et al., 2004, in press; Masten & Coatsworth, 1995).

In Figure 19.1, several of these complex models are illustrated. Figure 19.1g shows transactional, bidirectional effects over time between psychopathology and competence in a cross-lagged model that controls for the stability within each domain of behavior. Figure 19.1h also illustrates transactional effects but emphasizes that the transactions occur within the measurement window at each point in time and carry forward the effects of these interactions on each domain of behavior. In models of this type, popular among systems theorists, the association of competence and psychopathology would be expected to increase over time as a result of ongoing bidirectional influences (cf. Sameroff & Fiese, 2000). Figure 19.1i illustrates a cascade effect, where problems in one domain undermine competence, which in turn causes a worsening of symptoms in the original problem domain but also causes problems in a different psychopathology domain, thus affecting a third aspect of behavior. Cascade (or similar progressive) models conceptually require consideration of three or more domains of behavior across three or more points in time.

In the case of disorders characterized by conduct problems and linked with academic failure, evidence suggests that conduct problems and cognitive problems co-occur long before a disorder can be diagnosed and before children enter school (Hinshaw & Anderson, 1996). As noted, once children enter school, evidence suggests that antisocial behavior undermines achievement, and later, in secondary school, that academic failure is associated with worsening behavior. Clearly, this could be a progressive or cascade effect, though there are virtually no studies that directly test effects from one domain to another back to the first over time, controlling for all the initial covariance.

There also is evidence to suggest that internalizing symptoms show reciprocal linkages over time with peer social adjustment, though again, very few data with adequate controls for initial covariance exist (Harrington & Clark, 1998; Lewinsohn, Rohde, Klein, & Seeley, 1999; Masten & Coatsworth, 1995; Pine, Cohen, Gurley, Brook, & Ma, 1998; Rubin et al., 1998; Rubin, Chen, McDougall, Bowker, & McKinnon, 1995). However, studies using at least two

time points of data and controlling for initial levels of internalizing symptoms have shown peer status (Kiesner, 2002), sociability (Chen, Li, Li, Li, & Liu, 2000), popularity and friendship status (Nangle, Erdley, Newman, Mason, & Carpenter, 2003), and overall social competence (Cole et al., 1996) to predict later internalizing symptoms across diverse age ranges and sample contexts. There is more limited evidence in the opposite direction, that is, from internalizing symptoms to later social competence, controlling for initial levels of the latter construct. For example, Cole et al. found little evidence for such an effect using structural equation models over a 6-month interval, although the authors note that the very high stability of their social competence latent variable may have added to the difficulty of such a search.

It can be argued that a true cascading effect requires measurement of three constructs across three time points to account for concurrent and homotypic associations throughout the entire model. Although much of the empirical evidence reviewed here on links between competence and symptoms does not fall into such a category, there are intriguing examples of cross-domain links that seem best classified as developmental cascades. For example, a study by Mesman et al. (2001) used SEM to examine links among early preschool behavioral problems, social problems at school entry, and internalizing and externalizing problems in preadolescence. Using parent-reported behavioral checklist data, as part of their overall model for boys the authors found significant paths from time 1 aggression to time 2 social problems and also from time 2 social problems to time 3 internalizing problems. Time 1 anxious and withdrawn/depressed symptoms were included in the model. Although Mesman et al. were unable to include a full set of control variables, they establish compelling cross-domain links that are consistent with existing research on the development of internalizing problems (e.g., Panak & Garber, 1992; Rubin, Hymel, Mills, & Rose-Krasnor, 1991).

Cascade and progressive models resemble longitudinal mediation models, which also require (ideally) three variables and three time points and control for all the relevant continuity and concurrent correlations (Cole & Maxwell, 2003). The primary difference is in the goals of these models. Mediation models attempt to account for the association between two variables at two different points in time through a variable that represents an intervening process ($X_1 \rightarrow M_2 \rightarrow Y_3$). Cascade models attempt to account for the spread over time of success or failure in one domain to success/failure in multiple other domains over time ($X_1 \rightarrow Y_2 \rightarrow Z_3$); although the second variable in a se-

quence could be construed as a mediator (if a significant portion of the variance in Z explained by X is accounted for by Y), the focus of the cascade model is on explaining the effect of X on multiple later domains of behavior. In fact, in cascade models, there often is an interest in the mediators of each step in the progression (what processes mediate X effects on Y and also Y effects on Z).

INTERVENTIONS TO PROMOTE COMPETENCE AND REDUCE PSYCHOPATHOLOGY

Understanding how and why competence and psychopathology are connected in individual development has important implications for practice and policy, particularly given the twin societal goals of increasing competence and reducing the psychological, social, and economic suffering associated with psychopathology. If there is a common cause, then preventive intervention efforts that address the cause will serve both goals. If changing competence alters the subsequent risks for various problems and disorders, then prevention efforts to promote competence may be effective ways to prevent psychopathology or ameliorate its impact. If symptoms of psychopathology erode the achievement of developmental tasks, then early detection and treatment is important, not only for the relief of suffering related to the symptoms, but also to prevent further damage in the development of competence. Once the interference in competence is under way, it will be important to address the competence problems as well as treat the disorder; otherwise, there could be later consequences in competence or psychopathology domains. In the case of core developmental tasks, significant interference may have serious repercussions for future developmental tasks, as achieving some mastery of tasks in one period of development appears to serve as a foundation for attaining future competence. Thus, the developmental timing of interventions and also the nature of assessments pertinent to any kind of action or evaluation will be important.

Prevention and Competence

Over the past decade, three major trends are evident in the preventive intervention literature in regard to competence in developmental psychopathology. First, there has been a shift in how prevention scientists conceptualize interventions and what the primary goals and foci of interventions

are. Contemporary intervention design and evaluations tend to focus as much attention on changing proximal mediating developmental processes as they do on achieving distal outcomes of preventing psychopathology. This has illuminated more clearly and reinforced a general competence, or wellness-enhancement, model for preventing problem behaviors (Cowen, 1991, 1996; Masten & Coatsworth, 1998; Weissberg & Greenberg, 1998). Second, a resilience framework for prevention and intervention has been articulated for children at risk due to high adversity exposure and other negative circumstances (Cicchetti, Rappaport, Sandler, & Weissberg, 2000; Coie et al., 1993; Cowen, 2000; Kumpfer, 1999; Luthar & Cicchetti, 2000; Masten, 1994, 2001; Masten & Coatsworth, 1998; Masten & Garmezy, 1985; Masten & Powell, 2003; Masten & Reed, 2002; Rolf & Johnson, 1999; Sandler, Wolchik, Davis, Haine, & Ayers, 2003; Weissberg, Kumpfer, & Seligman, 2003; Wyman, 2003; Wyman, Sandler, Wolchik, & Nelson, 2000; Yates & Masten, 2004). Third, there is growing attention to developmental theory in the design of preventive interventions, with a particular eye toward developmentally strategic timing and approach (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1992b, 1999; Coie, Lochman, Terry, & Hyman, 1992; Kellam & Rebok, 1992).

Preventive interventions have been criticized for having a deficit orientation and for emphasizing youth problems (Benson, 1997; Lerner & Benson, 2003; Pittman & Cahill, 1991), which purportedly leads to a focus on problems over health, competence, and well-being. Although this criticism is valid in some respects, mainly in that some early-generation programs designed to prevent mental health problems did focus too strongly on trying to prevent singular problem outcomes (drug use, Conduct Disorder/juvenile delinquency), a review of the history of prevention theory and research indicates that enhancing and promoting competence, well-being, and health have *always been a hallmark of this approach*.

As noted in the history section, prevention of mental illness and promotion of mental health began to emerge as a national priority in the late 1950s and early 1960s. President John F. Kennedy (1963), in his "Message on Mental Illness and Mental Retardation to the Congress of the United States" in 1963, described prevention as "far more desirable," "far more economical," and "far more likely to be successful" than treatment-focused approaches. The salience of prevention was further enhanced by the President's Commission on Mental Health during the Carter presidency. One important result of this commission was a report from the Task Panel on Prevention (1978), reviewing

the extant literature, that outlined definitions of primary prevention of mental health and concluded that there was evidence indicating that some programs worked. Taking a broad public perspective, the report pointed to competence enhancement as a fundamental aspect of prevention, specifically noting that prevention was (1) proactive, meaning that it seeks to build adaptive strengths, coping resources, and health in people (e.g., *competence*) rather than containing already manifest deficits; (2) about total populations rather than individual cases; (3) relying on intervention strategies of education and social engineering rather than therapy and rehabilitation; and (4) founded on the premise that helping people develop the personal and environmental resources for coping is the best of all ways to ward off maladaptive problems. Another major outcome of this report was the establishment of a prevention office in the National Institute of Mental Health. Clearly, this report provided political impetus for promoting prevention; however, at the time, the strength of the scientific evidence supporting the claims for prevention was still weak.

Over the past few decades, primary prevention gained considerable scientific support through well-designed and carefully evaluated programs yielding empirical evidence that interventions can prevent occurrence of disorder. This early growth culminated in publication of *14 Ounces of Prevention* (Price, Cowen, Lorion, & Ramos-McKay, 1988), one of the first compendia of efficacious prevention programs. The project was conceived by the American Psychological Association's Board of Professional Affairs Task Force on Promotion, Prevention and Intervention Alternatives in Psychology. The task force selected the 14 model programs from 300 submissions. The programs were selected primarily on the basis of their outcomes but also to include diversity in targeted age and the settings in which the intervention was conducted. Of the 10 programs that represent interventions with children and adolescents, two are designed to alter broad systems that might influence youth adjustment (school, Juvenile Justice), and the remaining eight are programs that clearly are intended to enhance competence by building specific social, emotional, intellectual, or behavioral skills that are linked with successful adaptation. For example, Interpersonal Cognitive Problem Solving (Shure & Spivack, 1988) and Life Skills Training (Botvin & Tortu, 1988) are programs that teach generic cognitive problem-solving skills, personal, or social skills. Life Skills Training also teaches specific drug resistance and refusal skills, but these are embedded in a broader curriculum of social competence enhancement. Moreover, these programs emphasized building parenting competence as a method of influencing youth development.

Four of the programs contained some form of parental skill training. Empirical results were mounting that competence enhancement was an effective strategy for the promotion of adaptation, health, and the prevention of problem behavior.

Despite this accumulating data, conceptual confusion remained over whether a program should be defined as a prevention program or a competence enhancement program.

The premise that interventions should be founded on the dual goals of promoting competence and preventing problem behaviors (Cowen, 1986, 1994) was challenged by the influential Institute of Medicine (IOM; Mrazek & Haggerty, 1994) report *Reducing Risks for Mental Disorders: Frontiers for Preventive Intervention Research*. The authors of that report elected not to include mental health promotion efforts and distinguished them conceptually from prevention programs. They reasoned that the programs were not focused on "illness"; instead, the goals were to "enhance competence, self-esteem, and a sense of well-being, rather than to intervene to prevent psychological or social problems or mental disorders" (p. 27). Many prevention scientists criticized the decision to exclude health promotion and competence enhancement programs from a book intended to have profound scientific and political influence (Cowen, 1996; Durlak & Wells, 1997). Based on the results of a meta-analysis of 177 primary prevention programs, Durlak and Wells concluded that the IOM's decision to exclude health promotion may have been premature. Their results indicated that these primary prevention programs that were designed to strengthen children's affective, cognitive, and behavioral competencies showed effects for both problem reduction and competence enhancement that were comparable to other kinds of psychosocial interventions.

The distinctions made in the IOM report may have contributed to the competitive spirit between a positive youth development (PYD) frame and a prevention science frame. Fundamental to the PYD frame is the argument that "problem free is not fully prepared" (Pittman, 1991) and that a shift in focus is required for interventions with youth, de-emphasizing risk reduction and placing more importance on promoting youth development. Pittman, O'Brien, and Kimball (1993) contend that the required shift is more than semantic, because it has implications for program development, implementation, and evaluation. They acknowledge that "most of the strategies used to prevent substance abuse are, in fact, strategies that promote development—social skills, communication skills, self-awareness, family and community commitment" (p. 1). Other supporters of this approach have called for an exclusive focus on building assets, strengths, and protective factors (Benson, 1997).

PYD from a developmental systems view has been articulated in a series of books and papers written and edited by Lerner, Benson, Damon, and their colleagues (Damon & Gregory, 2003; Lerner, 2004; Lerner & Benson, 2003; Lerner, Dowling, & Anderson, 2003, 2005). This view emphasizes the multilevel and dynamic nature of adaptation and development (focusing on relations, regulation, and interactions of person with context), views youth as resources to be developed, and focuses on the processes by which valued, positive development and change occur: "The healthy and successful development of young people may be understood within the context of human evolution and of how adaptive regulation of person-context relations constitutes the basic process of ontogenetic change within the developmental systems" (Lerner et al., 2005, p. 861). They note that societies vary in expectations for what kind of behaviors will be judged as positive in development across the life span, much as we discussed earlier in terms of developmental tasks. At its best, successful youth development as conceptualized by these theorists results in *thriving* young people as well as thriving societies.

In prevention science, it appears that a shift has taken place so that the PYD and prevention science frameworks show a convergence of approaches (Catalano, Hawkins, Berglund, Pollard, & Arthur, 2002). This can be seen in publications resulting from the work of a task force appointed by Seligman when he was president of the American Psychological Association on Promoting Strength, Resilience and Health in Young People. This task force endorsed a broad model of intervention that encompassed the dual goals of promoting health and wellness and reducing problem behavior (Weissberg et al., 2003). In some respects, prevention research and competence enhancement have shifted back to a point at which they are seen less as competing frameworks and more as coordinated parts of integrated programming to improve the life conditions of youth (Catalano et al., 2002).

Promoting mental health (a goal of youth development programs) and preventing problems (a goal of prevention science) need not be competing endeavors (Catalano, Berglund, Ryan, Lonczak, & Hawkins, 2004). The primary tenets of these two approaches seem to derive from many common roots, they appear to have arrived at similar conclusions about the essentials for helping young people develop successfully, and both now reflect a developmental approach (Catalano et al., 2004). Currently, a substantial amount of work is being conducted on the measurement of the positive youth development constructs and other constructs from such perspectives as positive

psychology, human strengths/virtues, and positive character traits.

Conceptual Evolution of Preventive Interventions

Over the past decade, prevention science gained considerable theoretical and empirical ground. Not too surprisingly, this progress has paralleled advancements in developmental psychopathology and the study of resilience (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1999; Luthar, Chapter 20, this *Handbook*, this volume; Luthar & Cicchetti, 2000; Masten, 1999; Wright & Masten, 2005). Developmental psychopathology was described in the 1994 IOM report (Mrazek & Haggerty, 1994) as the "core integrative discipline for the knowledge base for prevention research" (p. 62). As basic research in developmental psychopathology has generated knowledge on the etiology, course, and plasticity of both adaptive and maladaptive development, prevention scientists have incorporated this knowledge in the design of their interventions. Consequently, many preventive interventions are better grounded in theory and research, with scientific justification for what they are doing.

Two kinds of theory-based approaches have emerged in prevention science, one focused on the problem and the other focused on the intervention. A "theory of the problem" is a developmental, explanatory theory of etiology, and a "theory of the intervention" specifies what needs to be changed and how it will be changed (Kellam, Koretz, & Moscicki, 1999). In both cases, clearly articulated developmental models are now more common (e.g., Conduct Problems Prevention Research Group, 1992, 2002; Lacourse et al., 2002; Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002); researchers often think of their interventions as "interactions with development" (Coie et al., 1993; Kellam & Rebok, 1992; Tolan, 2002), as protective processes to promote resilience (Sandler et al., 2003), and as tests of developmental theory (Cicchetti & Hinshaw, 2002). This has meant more than simply developing a model of some risk and protective factors that precede a specified outcome in time; rather, it means that greater attention has been given to drawing from current understanding of complex etiological models with hypothesized causal and interactive and transactional processes and using them to inform a pragmatic model that can be used in intervention design and evaluation (Dishion & Patterson, 1999). Moreover, these models often address risk and protective *processes* rather than risk and protective factors, which had been the guiding model for prevention for so many years (Coie et al., 1993). Thus, interventions are designed to change interactive social or intrapersonal psychological processes that are

hypothesized to be associated with subsequent occurrence of problem behavior.

Incorporating developmental models in prevention has also illustrated the importance of influencing proximal processes that will, in turn, influence distal outcomes. The emphasis in developmentally informed preventive interventions is placed as strongly on the hypothesized mediating factors and processes (e.g., promoting competence or skill acquisition) as on the ultimate outcomes (reduced future risk-taking behaviors or psychopathology). Initial efforts in prevention research were directed at understanding whether a program worked based on evidence that they changed the distal outcomes. Second-generation prevention programs have shifted to understanding the mechanisms by which a program works. Therefore, in intervention models that hypothesize building competence as a means of preventing psychopathology, competence often shares equal footing with psychopathology.

A second important influence on the design of preventive interventions has come through widespread adoption of broad ecological-contextual-systems models of development and change that have dominated the field of developmental psychopathology, as noted earlier. The implication of these kinds of systems models is that interventions can be designed to address risk and protection within and across systems. Intervention designers assume that it will be more effective to intervene on multiple levels or in multiple systems rather than within single domains of interaction (Nation et al., 2003). This approach also suggests that one can alter the environment or system that helps to maintain the behaviors. With respect to competence promotion programs, this might mean that changes to families (parent training, changing family functioning) or schools (structural and curriculum changes) might be important ways of reinforcing and maintaining cognitive, affective, and behavioral changes that are achieved through interventions directly with individuals.

Developmental psychopathology has also reinforced the need to examine competence and psychopathology, risks and assets, vulnerability and protection together to fully understand adaptation in development. For prevention, this means that exclusive focus on one or the other is likely to reduce the efficacy of an intervention or to overlook many possible targets for intervention or change leverage. The need to attend to both risk and protection has been a central tenet in prevention research (Coie et al., 1993), and recent evidence suggests that to maximize preventive effects, it would be strategically wise to focus on both positive and negative processes and outcomes (Pollard, Hawkins, & Arthur, 1999).

Model Prevention Programs with an Emphasis on Competence

The advancements made in prevention science over the past decade are reflected in the model programs that are promoted by federal agencies (see relevant Web sites of the agencies) such as the Center for Substance Abuse Prevention and the Substance Abuse and Mental Health Services Administration or Blueprints for Violence Prevention (Mihalic, Fagan, Irwin, Ballard, & Elliott, 2004), supported by the Office of Juvenile Justice and Delinquency Prevention. Careful examination of the theoretical underpinnings and intervention strategies of these programs does not reveal much support for the idea that prevention is primarily problem- and risk-oriented, as critics have sometimes suggested (noted earlier). Many of the programs are competence enhancement programs that emphasize building positive skills such as problem solving, self-awareness, effective communication, and conflict resolution as the proximal targets of the intervention. In the next section, several examples are provided to briefly illustrate the emphasis on competence characteristic of these model programs, which have demonstrated success in promoting development and reducing problems. Of course, these programs cannot possibly reflect the full extent of evidence-based competence promotion programs. However, these examples serve to highlight advancements occurring in competence promotion and prevention science over the past decade, in their theoretical clarity about the model of etiology and intervention underlying the program and their emphasis on development and context.

Life Skills Training Program

One of the most well-researched and -disseminated intervention programs with a focus on competence is the Life Skills Training program (Botvin & Griffin, 2004; Botvin & Tortu, 1988), a school-based competence promotion program that targets middle school and junior high school youth. The intervention is based on social learning theory (Bandura, 1986) and problem behavior theory (Jessor & Jessor, 1977), both of which posit that individuals who lack general interpersonal and coping skills show greater vulnerability to various influences that lead to substance use. Theoretically, building life skill and general competencies will protect youth from maladaptation. The program is delivered by classroom teachers who use traditional didactic teaching methods, group discussion, demonstration, and cognitive-behavioral skills training techniques to teach students personal self-management skills, social skills, and the consequences of drug use, accurate information about

normative drug use, techniques used by media and advertisers to promote cigarette and alcohol use, and peer resistance skills. Extensive evaluation indicates generally strong effects with respect to alcohol, marijuana, and tobacco that have been replicated across sites and ethnically diverse samples (Botvin & Griffin, 2004; Botvin, Griffin, Diaz, & Ifill-Williams, 2001; Botvin, Mihalic, & Grotspeter, 1998). Studies have also supported (though not consistently) the effects of the intervention on hypothesized mediating variables (competence), including assertiveness, social skills, decision making, and problem solving (Botvin, 2000).

Promoting Alternative Thinking Strategies

The Promoting Alternative Thinking Strategies program is a comprehensive school-based program for promoting emotional and social competencies and reducing aggression and behavior problems in elementary-age children. The program is designed to be used by educators and counselors as a multiyear prevention model, applied universally to all students. It was developed specifically to promote social and emotional competence as a strategy for preventing or reducing future behavior problems (Greenberg, Kusche, & Mihalic, 1998). The program integrates five conceptual perspectives in a multilevel systems model of development and change to focus on building protective processes (e.g., emotional awareness and problem solving) that will decrease maladaptive behavior. Teachers are given extensive training to change the way they attend to children's behavior and reinforce and support effective socialization patterns. Results from clinical trials with groups of regular education and special education youth indicate that the program increases mediating competence factors and decreases distal outcomes of behavior problems. At 1 year postintervention, youth who received the intervention showed less internalizing and externalizing symptoms by teacher report and less sadness/depression and fewer conduct problems according to self-report (Greenberg & Kusche, 1998; Greenberg, Kusche, Cook, & Quamma, 1995).

The Incredible Years: Parent, Teacher, and Child Training Series

The Incredible Years series (Webster-Stratton et al., 2001) is a set of three comprehensive, developmentally based interventions that are designed to work together to promote emotional and social competence in children ages 2 to 8 who are at risk for (selective) or already presenting with (indicated) aggressive, defiant, oppositional, and impulsive behavior. The parent-training curriculum serves as the primary element of the Incredible Years series, with optional

teacher and child training. It is a flexible intervention program that has been implemented in a variety of settings (e.g., schools, Head Start classrooms, community centers). The parent program consists of three interrelated components, including the core component that consists of parent training for 12 to 14 weeks, founded on social learning and attachment models of development (Webster-Stratton, 2001). Based in the empirical literature reflecting parenting practices as critical components to the development of conduct problems in children and adolescents (e.g., Deater-Deckard, Dodge, Bates, & Pettit, 1996; Dishion & Loeber, 1985), the program uses videotapes, didactic presentations, and group discussion to enhance parenting skills, such as empathy and reinforcement skills, use of nonviolent disciplinary and child management practices, monitoring, problem-solving strategies, and responding in clear and predictable ways to child behavior. The other two components focus on teaching parents how to foster school readiness and skills of their own for dealing with depression and marital problems (Webster-Stratton et al., 2001). Teacher-training components include a 6-day workshop that trains teachers, counselors, and other school personnel in effective classroom management techniques aimed at reducing problem behavior in the classroom and also promoting positive relationships, strengthening child social skills, and encouraging effective interactions with parents. The child training program is intended to enhance children's appropriate behavior in the classroom (e.g., compliance, turn-taking), promote social skills and positive peer interactions, and develop age-appropriate conflict-resolution skills.

The core parent training program of the Incredible Years series has been evaluated extensively over the past 20 years, and results from six randomized clinical trials indicate significant improvements on parental management skills and reductions in child behavior problems (Webster-Stratton, 1985, 1990a; Webster-Stratton & Hammond, 1997) and lasting improvements for at least 3 years postintervention (Webster-Stratton, 1990b). The child-training component has also been evaluated in two clinical trials and found to be efficacious in improving social skills, conflict management strategies, and overall interactions with peers (Webster-Stratton & Reid, 1999). Evaluations of the separate components of the Incredible Years program have demonstrated effectiveness in changing child social competencies, parent competence, and teacher competence (management skills). A recently published study reported on additive effects across the three parent, teacher, and child programs demonstrating interesting main and interactive effects (Webster-Stratton, Reid, & Hammond, 2004). Results suggest that all intervention combinations had significant effects in lowering child

behavior problems with parents, teachers, and peers as compared to controls. Conditions that included parent training had greatest effects on parenting skills, and conditions that included child training had significant effects on youth behavior at home, at school, and with peers. Findings also indicated that parent training decreased youth negative behaviors at home and school but did not enhance prosocial behaviors. Interestingly, parent- and child-training-only conditions also influenced teacher behaviors in the school. Purportedly, the changes in youth behavior resulting from child or parent training influenced the teachers to improve management practices. This finding suggests the critical nature of a systems perspective that encourages close examination of how intervention effects at one level of analysis or in one domain (e.g., individual) might influence behavior at other levels or other domains (e.g., school). Youth social competence can be influenced by direct intervention to improve parenting.

Skills, Opportunities, and Recognition

The Skills, Opportunities, and Recognition program, formerly known as the Seattle Social Development Project (Hawkins, Von Cleve, & Catalano, 1992), is a multicomponent program designed to enhance protection and reduce risk in the school and family environments. Based on the social development model (Hawkins & Weis, 1985), which is predicated on social control and social learning theories, the program hypothesizes that promoting positive social bonds to school and family (e.g., enhancing competence as attachments to parents and important others, such as teachers) will reduce the likelihood of problem behaviors. To create and strengthen those bonds, social development theory proposes that the contexts of family and school must help youth develop the skills needed to be successful (e.g., academic competence), provide ample opportunities for youth to practice and refine their skills, and consistently reinforce youth for behaving competently. Classroom teachers are trained in proactive classroom management skills, interactive teaching, and cooperative learning. In first grade, direct competence enhancement included having teachers provide classroom-based communication, conflict resolution, and decision-making and negotiation skills training. In sixth grade, teachers taught refusal skills. The intervention also targeted parental competence, with optional parent-training programs throughout the child's schooling. The parent-training component emphasized teaching child behavior management techniques (monitoring and consistent discipline) to parents in grades 1 and 2; academic support (establishing home learning environment, helping their child develop reading and math skills)

and family-school communication; and parent reinforcement of antidrug and antidelinquency messages in fifth and sixth grades. The study was conducted as a controlled trial in which eight urban and ethnically diverse schools in the Seattle area were assigned to receive the intervention or not (Hawkins, Catalano, et al., 1992). Youth began receiving the intervention in first grade. Results of ongoing evaluations have found that very early at grade 2, boys who were exposed to the intervention had lower levels of problem behaviors (aggression, externalizing behaviors) and girls had lower levels of destructive behaviors. By follow-up at grade 5, program effects demonstrated differences between program youth and controls on the purported mediators of family management practices, family bonding and commitment, and bonding to school. Intervention youth also showed lower levels of alcohol and delinquency initiation. By grade 11, program youth showed less violence, sexual activity, and fewer times drunk. Ongoing, long-term evaluations have demonstrated that the effects of changing early school bonding may persist well beyond the elementary school years (Hawkins, Guo, Hill, Battin-Pearson, & Abbott, 2001) and that competence-enhancing interventions in early childhood may have long-term promotive effects on positive adult functioning (Hawkins, Kosterman, Catalano, Hill, & Abbott, 2005).

Summary Comments on Model Programs That Promote Competence to Prevent Psychopathology

These successful competence promotion and psychopathology prevention programs provide examples of efforts to change competence in order to reduce future psychopathology, including internalizing and externalizing behavior, risky behavior, and substance use. Longitudinal data have suggested that there may well be more intermediate, mediating processes between specific skills or achievements and distal outcomes. For example, drug use may be mediated by psychological well-being (Epstein, Griffin, & Botvin, 2002; Griffin, Scheier, Botvin, & Diaz, 2001) and social expectancies (Griffin, Epstein, Botvin, & Spoth, 2001). Mediational analyses directed at delineating the intervening processes of change are now viewed as a hallmark of good prevention program evaluation (MacKinnon & Dwyer, 2003; MacKinnon, Taborga, & Morgan-Lopez, 2002) and provide the most complete test of the intervention's developmental model (Cicchetti & Hinshaw, 2002; Hinshaw, 2002a). At the same time, there remains very little long-term evidence documenting how the changes that result from an intervention lead to lasting improvements, often in multiple domains of both competence and symptoms. In many ways, this lack of evidence parallels the vast

“black box” of data on long-term change in development, how developmental cascades occur, and the causal processes underlying the connections of competence and psychopathology over time.

A Note on Treatment and Competence

Prevention, broadly conceived, encompasses some elements of treatment that are designed to prevent recurrence, worsening of problems, or further complications of a disorder or problem. The literature linking competence and psychopathology, highlighted in this chapter and documented in many other chapters of this compendium, however, suggests both that psychopathology can have damaging effects on competence and that current competence as evidenced by impairment is often a strong indicator of prognosis, the level of risk for complications such as suicide or school failure, and even of the likely success of a given intervention. These observations suggest that attention to competence in the formulation of a treatment plan is essential, as has been noted by many clinicians and scholars in the treatment field.

Intervention Designs to Test Theories Linking Competence and Psychopathology in Development

Interventions to alter the quality of adaptation in development, whether conceptualized as positive youth development, prevention, or treatment, offer opportunities to test different models of how competence and psychopathology are related. Experimental studies, with random assignment to intervention or enhancement group, provide powerful designs for testing hypotheses about causal effects among competence and psychopathology domains of behavior, as well as potential common causes and mediators. The potential of experimental intervention research for illuminating the processes of adaptation in development and vice versa has been noted for some time (Cicchetti & Toth, 1992b; Masten, 1994). To date, however, the potential of experimental designs to illuminate how and why competence and psychopathology are associated in development has not been fully realized. Most research, perhaps understandably, has been focused on what works, for whom, and how to improve these effects, rather than the significance for developmental science and psychopathology.

An interesting case in point is provided by the longitudinal intervention study implemented in the 1980s by the Seattle Social Development Research Group (Hawkins, Catalano, Kosterman, Abott, & Hill, 1999; Hawkins et al., 2003). This important study, described earlier, was embedded in a large panel study of antisocial behavior, which it-

self has provided a remarkable look at naturally occurring growth patterns in behavior over time, particularly in regard to risky and antisocial behavior (Hawkins et al., 2003). The intervention was successful at its conclusion (end of elementary school) and on long-term follow-up (end of high school and beyond). Though the design was not a completely randomized experiment, the findings provided compelling evidence that the intervention beginning early and continuing through elementary school worked to reduce the risk of various negative outcomes, and did so, at least in part, by means of school bonding, which was the theory-driven target mediator of the intervention. This finding has been interpreted by the investigators and others as good evidence for the efficacy of their model of antisocial behavior and their model of intervention. However, it is also interesting to note (Masten, 2004) that the treatment effects were not apparent for a period of time during middle school, in the transition to adolescence, a time of biological, behavioral, social, and contextual change. The results of the study could be discussed in relation to their significance for developmental theories of adolescence (see Steinberg et al., Chapter 18, this *Handbook*, Volume 2). It is possible that treatment effects were obscured for a time by individual differences in growth and response to contextual changes of this period, much like relative height and strength are obscured by variations in pubertal change during the same period of time.

One of the best examples of an experimental intervention study that has made a significant contribution to developmental theory is provided by van den Boom (1994, 1995) in her studies of irritable infants. Mothers in the experimental group were trained to be more sensitive and attuned to their babies, in accordance with attachment theory (using strategies developed by van Ijzendoorn and colleagues; van Ijzendoorn, Juffer, & Duyvesteyn, 1995), and their babies were not only more securely attached but also more competent over time. These findings offer compelling evidence in support of key aspects of attachment theory concerning the causal role of sensitive care for secure attachment and secure attachment for later development (Sroufe, 1979).

CONCLUSIONS AND FUTURE DIRECTIONS

The theoretical and empirical literature on competence and psychopathology in development examined in this chapter is indicative of progress toward a more integrated understanding of adaptation in development. This progress underscores the potential of research linking competence

and psychopathology to contribute to theories of normal development, as well as the classification, etiology, course, prevention, and treatment of psychopathology. In this section, we highlight this progress and the implications of the current literature on competence and psychopathology for classification, practice, and future research.

Signs of Progress for an Integrated Approach to Adaptation in Development

There are multiple signs of progress reflected in this chapter (and also in many other chapters of this volume) toward the goal of delineating how competence and psychopathology are linked. As evident across many of the chapters collected here, there have been improvements in theory, research design, and the simple volume of relevant work. Serious consideration is being given to the meaning and significance of impairment in relation to diagnosis and competence. More nuanced studies of developmental tasks are under way. Research on resilience has expanded so much that a separate chapter on resilience was required in this volume. There are many more longitudinal studies in the literature that take advantage of repeated measures, multiple informants and methods, and powerful statistical tools, such as growth curve modeling and structural equation modeling, to test causal models that control for within-time correlations and error and help sort out the direction and timing of cross-domain effects. Models are more dynamic. Person- and variable-focused approaches are combined for testing change over time within individuals. Mediating processes that may explain why competence influences symptoms or vice versa are being considered, both conceptually and empirically. Samples are larger in some cases, allowing for more comprehensive models to be tested. Prevention science that encompasses the constructs of competence, psychopathology, risk, resilience, and promotion is burgeoning. There is a growing group of investigators, practitioners, and policymakers focused on competence, strengths, positive youth development, the practice of positive psychology, and resilience.

It is striking to note the growing attention to positive aspects of psychology and youth development that have occurred over the past decade. Positive psychology gained enormous momentum under the leadership of Seligman (particularly when he was president of the American Psychological Association) and others who have published articles and books, sponsored meetings, formed task forces, founded centers, and in other ways promoted positive perspectives on human behavior (Linley & Joseph, 2004;

Lopez, 2002; Seligman, 2002; Seligman & Csikszentmihalyi, 2000). These scholars recognized the kinship of developmental research on competence and resilience, including chapters on competence and resilience in development in special issues and books on positive psychology (Masten, 2001; Masten & Reed, 2002; Yates & Masten, 2004).

The interest in positive youth development also expanded rapidly in recent years, underscoring the importance of society and communities investing in the development of competence in young people (Lerner et al., 2003, 2005; Smith, Steinman, Chorev, Hertzog, & Lerner, 2005). In light of the surge of interest in resilience and prevention already under way, the rise of positive psychology and positive youth development may signify a general renaissance in competence theory and research.

Improving Assessment, Diagnosis, and Classification

The salience of competence in research and practice related to resilience, prevention, positive psychology, and positive youth development appears to have had a considerable effect on the medically oriented tasks of assessing, diagnosing, and classifying psychopathology. Masten and colleagues (Masten & Gewirtz, 2005; Masten & Reed, 2002; Wright & Masten, 2005; Yates & Masten, 2004) have noted the transformational impact of resilience research in developmental psychopathology for the practice of psychology in terms of changing the way that the mission, models, measures, and methods are conceptualized and implemented. The goals of intervention are more often conceived in terms of positive goals and competence achievement; models include competence as well as symptoms, assets as well as risks, protective factors as well as vulnerabilities; measures (likewise) include strengths and resources as well as problems and risks; and strategies target risk prevention and competence promotion, bolstering protective systems and adding assets (in child, family, school, neighborhood, and other contexts), along with the many traditional methods of ameliorating and treating problems in the child and family. This transformation was forecast early in the history of developmental psychopathology (Garmezy, 1971), and its occurrence has been noted by many scholars (Cicchetti et al., 2000; Coie et al., 2000; Lerner et al., 2003; Luthar, 2003, Chapter 20, this *Handbook*, this volume; Masten & Gewirtz, 2005; Shonkoff & Meisels, 2000; Weissberg et al., 2003).

Much work has been done to develop tools for differentiating and assessing competence, symptoms, and various as-

pects of impairment. There have been serious efforts toward the development of distinct criteria for adaptive functioning and context to go along with diagnostic criteria for disorder.

Nonetheless, evidence strongly suggests that it would be very useful to develop better tools for tracking competence over time in relation to psychopathology symptoms and other important variables. There are some practical issues to keep in mind with such a goal, including the often difficult task of assigning co-occurring disability or impairment to particular symptoms and management of clinician workload. However, work by Costello, Angold, and others with the CAPA interview and impairment assessment has shown (albeit in an epidemiological research context) that such goals are attainable.

Evidence also suggests that further revision of the diagnostic and classification systems is needed in regard to the definition of mental disorder, specification of disorders, and parsing of axes on which to diagnose and classify individuals. We can see clear benefits in the WHO *ICD* system that explicitly decouples impairment from disorder, though noting that this framework poses more of a challenge for developing symptom criteria that accurately capture the targeted phenomena; perhaps advances in molecular genetics and neuroscience will contribute to this effort. In the *DSM* system, in the short term we are sympathetic to the calls of Gruenberg and Goldstein (2003), among others, for a revised Axis V that assesses functional impairment as distinct from level of symptomatology. Ideally, such a revised "impairment axis" for the diagnosis of adaptive functioning status could be segmented into multiple dimensions, building on our growing body of knowledge about competence and developmental tasks from the developmental sciences, as well as the research on psychosocial disability. Of course, such efforts need to consider practicality and clinician time; however, given the demonstrated importance of impairment in prognosis and treatment planning, work to develop better tools and ensure their proper use in the field should prove to be a good investment.

Strategic Developmental Policy and Prevention

The traditions of competence, psychopathology, and prevention science as described in this chapter appear to be converging through the integrative and explanatory power of a developmental perspective, and there appears to be benefit all around. Here too, however, there is clearly room for growth. There are still many gaps in knowledge of de-

velopmental pathways leading toward and away from specific problems and disorders that could inform intervention and policy. Yet, there is also evidence suggesting robust pathways that are not yet integrated into interventions design. Interventionists may not build their models on the most up-to-date theory or evidence, and developmental theorists and investigators not directly engaged in intervention may fail to keep up with state-of-the-art intervention findings that could refute or enrich their theories.

A more complete picture of developmental pathways encompassing both competence and psychopathology would provide a better foundation for strategic prevention and treatment. For example, the knowledge base about early starter pathways in antisocial behavior has led to prevention studies with very young children that focus on addressing early problems in self-regulation and seek to move children onto competence pathways (Shaw, Dishion, Supplee, Gardner, & Arnds, in press). Different strategies are employed with these preschoolers as compared to the school-age children in other developmentally designed interventions, such as FAST Track (Conduct Problems Prevention Research Group, 1992). Cascade models suggest that it may be important (when more is known about timing and sequencing of such progressions) to intervene early to treat one problem before it affects other critical domains of adaptation. If the cascade has already occurred, treating the starting problem (e.g., aggression), no matter how successfully, may not affect the long-term consequences of the progressions (academic or social difficulties) that have already been precipitated. Interventions would be most effective if the right domains are addressed with strategic timing and methods, and experimental tests of interventions based on cascade models would provide strong evidence pertinent to such etiological models.

It is also conceivable that competence promotion will work regardless of natural patterns of influence among dimensions of competence and psychopathology. Developmental task expectations and reinforcements are inherently powerful, and successes in these desirable domains of behavior could redirect development in positive directions, regardless of how young people got on the wrong road to begin with. Late bloomers in the resilience literature (Masten et al., 2004; Masten, Obradovic, & Burt, in press; see also Luthar, Chapter 20, this *Handbook*, this volume) and dramatic recovery in natural experiments (Cicchetti, 2003) suggest that recovery to good adaptation occurs among children who get off-track developmentally, particularly when major changes occur in the favorableness of their adaptive systems and context.

Dynamic, Multilevel, Multidisciplinary Approaches to Adaptation in Development

As evident throughout this second edition, advances in genomics, developmental neuroscience, statistics, and many other research areas and strategies, combined with advances in multidisciplinary collaboration and the growing availability of rich, longitudinal data sets, is revolutionizing the nature of research and theory in developmental psychopathology. These changes will benefit the process of integrating theories and applications of developmental adaptation studies and may shed new light on the undoubtedly complex processes that account for the striking patterns observed in competence in relation to psychopathology. We expect to see much more longitudinal research designed to test how and why success in developmental tasks is related to the etiology, symptoms, course, and recovery from psychopathology and also its prevention and treatment.

Research in developmental psychopathology is generally expanding to encompass more levels of analysis and interaction. Therefore, we expect that the study of competence in relation to psychopathology over the next decade will expand to include competence in systems beyond the individual and family, such as the competence of schools and systems of care for children (e.g., Masten, 2003). In the other direction, we expect there to be much more attention to the systems within the individual child as they relate to each other and to behavior and experience, such as gene expression, brain function, hormonal systems, and their development (e.g., Dahl & Spear, 2004; Steinberg et al., Chapter 18, this *Handbook*, Volume 2). These new frontiers may take the study of adaptation in surprising new directions.

Stakeholders in Competence

Parents, children, societies, and the global community all have a stake in the quality of adaptation achieved by individuals in development. There are unique developmental tasks across communities, cultures, and nations, but also many common expectations for children as they grow up. And the world grows smaller every day as a result of exploding technology for sharing knowledge and communication. Psychopathology, in many forms, under many names in different lands, interferes with the development of competence and the human and social capital that promotes competence. The psychopathology of adults may undermine the competence and functioning of caregivers and relationships that constitute critical protective systems for child development. Developmental task achieve-

ment sets the stage for successful individual development and also healthy societies. Negotiating and mastering such tasks requires an extraordinarily complex orchestration of processes, often codirected by children and people in their contexts, always changing over the course of development. Yet, competence as indexed by success in age-salient developmental tasks appears to be robust under many challenging circumstances and may function as the best general inoculation or preparation for the vicissitudes of life, akin to physical health and fitness. Understanding the development of competence and its role in normative and deviant development is a key task for developmental psychopathology and for prevention science; at the same time, it is a valuable investment for stakeholders in successful human development.

CHAPTER 20

Resilience in Development: A Synthesis of Research across Five Decades

SUNIYA S. LUTHAR

HISTORICAL OVERVIEW OF CHILDHOOD RESILIENCE	740
RESILIENCE RESEARCH: CENTRAL FEATURES	742
Vulnerability and Protective Processes	743
Understanding Underlying Processes	748
Resilience and Related Constructs	750
Resilience and Related Disciplines	751
VULNERABILITY AND PROTECTIVE PROCESSES: SUMMARIZING EXTANT EVIDENCE	753
Family Relationships: Effects of Maltreatment	754
Protective Family Forces: Attachment, Nurturance, and Support	755
Protective Parenting: Discipline and Monitoring	759
Coexisting Warmth and Appropriate Control	760

Underlying Processes and Other Potentially Important Dimensions: Future Research Needs	761
Communities: Effects of Violence	766
Protective Processes in Communities: Early Intervention and Schools	767
Peers and Social Networks	770
Neighborhoods	772
Individual Attributes: Malleability in Contexts	773
SUMMARY OF EVIDENCE AND FUTURE DIRECTIONS: RECONCEPTUALIZING RESILIENCE	780
Research Designs: Optimizing Selection of Risk Modifiers for Study	782
REFERENCES	783

In the field of developmental psychopathology, resilience, a construct representing positive adaptation despite adversity, has received increasing attention over the past several decades. Since its introduction in the scientific literature during the second half of the twentieth century, this construct has been increasingly recognized as one of considerable importance from a theoretical and an applied perspective. Theoretically, knowledge of all “deviant” or atypical processes has great potential to promote understanding of normative development (Cicchetti & Cohen, 1995). Resilience by definition encompasses atypical

processes, in that positive adaptation is manifested in life circumstances that usually lead to maladjustment. From an applied perspective, similarly, there is broad consensus that in working with at-risk groups, it is far more prudent to promote the development of resilient functioning early in the course of development rather than to implement treatments to repair disorders once they have already crystallized (Cowen, 1991, 1994; Knitzer, 2000a, 2000b; Luthar, Cicchetti, & Becker, 2000a; Rutter, 2000; Werner, 2000). Knowledge about resilient processes in specific at-risk circumstances can be critical in pointing to the particular issues that most urgently warrant attention in the context of particular types of adversity.

In this chapter, we describe the major developments in the field of resilience since its inception more than 40 years ago. The chapter is organized in four sections, the first one presenting a brief history of work on resilience. The second section is devoted to elucidating critical features of research on this construct, highlighting three sets of issues: definitions and operationalization of the two constructs at its core, protective and vulnerability factors; distinctions between the construct of resilience and related

Preparation of this chapter was funded in part by grants from the National Institutes of Health (RO1-DA10726 and RO1-DA11498, RO1-DA14385) and the William T. Grant Foundation. For her considerable help with background research and editing, I am most grateful to Pamela Brown; many thanks as well to Elizabeth Ekeblad and Chris Sexton at Teachers College and to Erica Shirley and Karen Shoum of the Yale Child and Family Research Group.

This chapter is dedicated to Chanchal Wadhwa and Zena Vijay-Kumar, two teachers who so generously gave of themselves in fostering adolescent resilience.

constructs, such as competence and ego resiliency; and differences between resilience research and related fields, including risk research, prevention science, and positive psychology.

The third section of the chapter is focused on major findings on vulnerability and protective factors. These are discussed not only in terms of the specific factors found to modify risk within three broad categories—attributes of the family, community, and child—but also in terms of factors that exert strong effects across many risk conditions and those more idiosyncratic to specific risk contexts. The final section includes a summary of extant evidence in the field along with major considerations for future work on resilience across the life span.

HISTORICAL OVERVIEW OF CHILDHOOD RESILIENCE

The roots of resilience research can be traced back to pioneering research with children of schizophrenics during the 1960s and 1970s. In studies intending to capture the etiology and prognosis of severe psychopathology, Norman Garmezy (1974) found that among these children at high risk for psychopathology was a subset of children who had surprisingly healthy adaptive patterns. Whereas these youngsters had been dismissed by scientists as being atypical cases, Garmezy and colleagues sought to identify factors associated with their unusually high well-being. This approach reflected a notable departure from the symptom-based medical models of the time in its focus on positive outcomes and the factors that foster them in the context of life's adversity.

Along with Garmezy, two other prominent scientists who studied resilience among children of schizophrenics at the time were E. James Anthony and Michael Rutter. Anthony (1974) described a set of "invulnerable" children who resisted becoming engulfed by a parent's psychopathology while still maintaining compassion for the affected parent. Rutter (1979) also identified a distinct subgroup of resilient children in this population, reporting them to be characterized by traits such as high creativity, effectiveness, and competence.

In research with groups other than families of schizophrenics, Murphy and Moriarty (1976) examined vulnerability and coping patterns in children exposed to naturally occurring stressors such as deaths or injuries in the family. Based on rich clinical observations, these authors described resilient youth as having several attributes in

common, including social charisma and the capacity to relate well to others, the ability to experience a range of emotions, and the ability to regulate the expression of these emotions.

Emmy Werner's (Werner & Smith, 1982, 1992, 2001) study of infants at risk on the Hawaiian island of Kauai is a landmark in the scientific study of resilience. The study was begun in 1954 with a cohort of all known pregnancies on the island, with several follow-up assessments that continue up to the present time. The earliest reports on this cohort showed that children manifested significant deficits when family poverty was accompanied by perinatal risk. Furthermore, effects of poverty status seemed to operate via disruptions in the quality of the caregiving environment, particularly instability and disorganization of the family. Major protective factors, distinguishing well-functioning at-risk children from those faring more poorly, included affectional ties with the family, informal support systems outside the home, and dispositional attributes such as sociability.

The 1980s saw the publication of several scholarly papers on resilience, two of which were particularly influential; one was a research report by Garmezy, Masten, and Tellegen (1984) at the University of Minnesota, and the other was an analysis of conceptual issues in the study of this construct by Michael Rutter (1987). The former reported on Project Competence, a study of competence among children who experienced life stressors (Garmezy et al., 1984). The conceptualization of major constructs, methods, and data analytic strategies in this article (described later in this chapter) came to serve as models for scores of subsequent research seeking to illuminate vulnerability and protective factors.

Rutter's (1987) article was seminal in clarifying major conceptual issues in the study of resilience. In this paper, he provided several examples of a particularly intriguing class of protective processes, those with interactive components (also examined by Garmezy et al., 1984). Boys, for example, reacted more severely to family discord than did girls such that being female was "protective," and having a supportive spouse was more strongly related to good parenting among ex-institutionalized women than comparison mothers. Rutter also provided one of the first discussions on the importance of identifying processes in resilience and delineated various ways via which risk effects can be reduced: by altering the *experience* of risk itself (e.g., preparing a child before hospitalization); by altering *exposure* to the risk (e.g., via strict parental supervision in high-risk environments); by averting *negative*

chain reactions (which serve to perpetuate risk effects, as harsh discipline perpetuates oppositionality); by *raising self-esteem* (through secure relationships and tasks well done); and through *turning points* or opportunities (such as entry into army service).

During the 1980s and early 1990s, there were several changes in conceptual approaches to studying the construct, two of which were particularly salient. The first concerned perspectives on the “locus” of resilience. In early studies in this area, the effort had been to identify personal qualities of resilient children such as autonomy or belief in oneself. As work in the area evolved, however, researchers acknowledged that resilient adaptation may often derive from factors external to the child. Three sets of factors thus came to be commonly cited as implicated in the development of resilience: attributes of the children themselves, aspects of their families, and characteristics of their wider social environments (Garmezy, 1987; Rutter, 1987; Werner & Smith, 1982, 1992).

The second change involved conceptions of resilience as potentially fluctuating over time rather than fixed forever. In some early writings, those who did well despite multiple risks were labeled “invulnerable” (Anthony, 1974). Recognizing that this term implied that risk evasion was absolute and unchanging, researchers gradually began to use the more qualified term “resilience” instead. Implicit in this change of terminology was the recognition that positive adaptation despite adversity is never permanent; rather, there is a developmental progression, with new vulnerabilities and strengths emerging with changing life circumstances (Garmezy & Masten, 1986; Werner & Smith, 1982).

A related qualifier was that children can seem resilient in terms of their behaviors but still might struggle with inner distress in the form of problems such as depression and anxiety. First reported in work on maltreated children (Farber & Egeland, 1987) and subsequently among inner-city adolescents (Luthar, 1991), this finding has since been replicated in various at-risk groups. Among children of depressed mothers, for instance, there is a distinct adaptation pattern involving adoption of the caretaker role: a kind of false maturity, which may initially appear to be healthy but is likely to have negative consequences over time (see Hammen, 2003; Hetherington & Elmore, 2003). In work with children of alcoholics, Zucker and colleagues (Zucker, Wong, Puttler, & Fitzgerald, 2003) found that children who showed little outward disturbance as preschoolers generally continued to show low behavioral deviance several years later. On the other hand, these preschoolers, initially

identified as resilient, came to show internalizing symptoms as high as those of the initially most troubled group. Recognizing that (1) children can retain their manifest resilience but still experience inner distress, and (2) internalizing problems, if left unattended, can eventually derail apparently resilient trajectories (Luthar & Cicchetti, 2000; Raver, 2002), scholars now underscore the need to consider the unique profiles, and the associated intervention needs, of youth who are behaviorally stellar but at the same time psychologically vulnerable (D’Imperio, Dubow, & Ippolito, 2000; Luthar & Zelazo, 2003; Zucker et al., 2003).

Finally, it was recognized that even considering only domains of behavioral competence, resilience is never an across-the-board phenomenon, but inevitably shows some domain-specificity. Much as children in general do not manifest uniformly positive or negative adaptation across different areas of adjustment, researchers cautioned that at-risk children, too, can display remarkable strengths in some areas but, at the same time, show notable deficits in others (Luthar, Doernberger, & Zigler, 1993). In view of the accumulated evidence, therefore, scientists have—prudently—begun to use more circumspect terms that specify domains in which resilience is seen, referring, for example, to educational resilience (Wang & Gordon, 1994) or emotional resilience (Denny, Clark, Fleming, & Wall, 2004).

By the turn of the century, the burgeoning popularity of the resilience construct was reflected not only in the number of scientific publications on this topic but also the breadth of at-risk circumstances examined. Several scholarly articles were published about critical conceptual issues in studying resilience and summarizing the research findings until that time (e.g., Cohler, Stott, & Musick, 1995; Luthar, 1993; Luthar & Zigler, 1991; Masten, 2001; Masten, Best, & Garmezy, 1990; Masten & Coatsworth, 1998; Rutter, 1993, 2000). Resilience was the focus of a special issue of the journal *Development and Psychopathology* (Cicchetti & Garmezy, 1993) as well as several books encompassing diverse topics and scientific methods (e.g., Cicchetti, Rappaport, Sandler, & Weissberg, 2000; Glantz & Johnson, 1999; Haggerty, Sherrod, Garmezy, & Rutter, 1996; Hetherington, 1999; Luthar, 2003; McCubbin, Thompson, Thompson, & Futrell, 1999; Rolf, Masten, Cicchetti, Nuechterlein, & Weintraub, 1990; R. D. Taylor & Wang, 2000; Ungar, 2004; Wang & Gordon, 1994). In terms of diversity of risks examined, by the year 2000, resilience had been examined in the context of adversities ranging from parental mental illness (Masten & Coatsworth, 1998), maltreatment (Cicchetti & Rogosch, 1997), and chronic illness (Wells & Schwebel, 1987), to socioeconomic disadvantage and associated risks

(Garmezy, 1993; Luthar, 1999; Rutter, 1979; Werner & Smith, 1982, 1992), community violence (Richters & Martinez, 1993), and catastrophic life events (O'Dougherty-Wright, Masten, Northwood, & Hubbard, 1997).

Alongside the rapid proliferation of studies on resilience, however, were increasing concerns about the rigor of methods used in this body of work (e.g., Cicchetti & Garmezy, 1993; Glantz & Johnson, 1999; Luthar, 1993; Rutter, 2000). In particular, critics alleged (and with good reason) that the literature on resilience reflected considerable confusion around pivotal constructs and definitions, about criteria used to label people as resilient, and about the definition and measurement of protective and vulnerability processes (Luthar, Cicchetti, & Becker, 2000a). Given the centrality of these notions and the fact that there are still some uncertainties about them in the field, they are discussed at some length in the section that follows.

RESILIENCE RESEARCH: CENTRAL FEATURES

Resilience is defined as a phenomenon or process reflecting relatively *positive adaptation despite experiences of significant adversity or trauma*. Resilience is a superordinate construct subsuming two distinct dimensions—significant adversity and positive adaptation—and thus is never directly measured, but is indirectly inferred based on evidence of the two subsumed constructs.

Considering the two component constructs in turn, risk is defined in terms of statistical probabilities: A high-risk condition is one that carries high odds for measured maladjustment in critical domains (Masten, 2001). Exposure to community violence, for example, constitutes high risk given that children experiencing it reflect significantly greater maladjustment than those who do not (Margolin & Gordis, 2000). Similarly, maternal depression is a risk factor in that children of mothers with depressive diagnoses can be as much as 8 times as likely as others to develop depressive disorders themselves by adolescence (Wickramaratne & Weissman, 1998).

In addition to discrete risk dimensions such as community violence, poverty, and parent mental illness, researchers have examined composites of multiple risk indices such as parents' low income and education, their histories of mental illness, and disorganization in their neighborhoods. Seminal research by Rutter (1979) demonstrated that when risks such as these coexist (as they often do in the real world), effects tend to be synergistic, with children's outcomes being far poorer than when any of these risks existed in isolation. Use of this cumulative risk

approach is exemplified in work by Sameroff and his colleagues (e.g., Gutman, Sameroff, & Cole, 2003; Sameroff, Gutman, & Peck, 2003). These authors computed a total risk score across 10 different dimensions, assigning for each one a score of 1 (versus zero) if the child fell in the highest quartile of continuous risk dimensions and, for dichotomous dimensions such as single-parent family status, if they were present in that child's life. Masten and colleagues (Masten, Morison, Pellegrini, & Tellegen, 1990) used a somewhat different approach to deriving total risk based on continuous scores; these researchers standardized the values on different risk scales and added them to obtain a composite.

Decisions regarding the use of single or multiple risk indices in resilience research depend on the substantive research questions. The former is used, obviously, when applied researchers seek to identify factors that might modify the effects of *particular* environmental risks known to have strong adverse effects, so as to eventually derive specific directions for interventions. Examples are parental divorce and bereavement; knowledge of what ameliorates the ill effects of these particular adversities has been valuable in designing appropriate interventions (C. R. Martinez & Forgatch, 2001; Sandler, Wolchik, Davis, Haine, & Ayers, 2003). Additive approaches are more constrained in this respect, precluding identification, for example, of which of the indices subsumed in the composite are more influential than others. On the other hand, composite risk indices generally explain more variance in adjustment than do any of them considered alone, and as noted earlier, they may be more realistic in that many of these risks do co-occur in actuality (Luthar et al., 2000a; Masten, 2001).

Positive adaptation, the second component in the construct of resilience, is adaptation that is substantially better than what would be expected given exposure to the risk circumstance being studied. In many studies of resilience across diverse risk circumstances, this has been defined in terms of behaviorally manifested social competence, or success at meeting stage-salient developmental tasks (Luthar et al., 2000a; Masten, 2001; Masten & Coatsworth, 1998). Among young children, for example, competence was operationally defined in terms of the development of a secure attachment with primary caregivers (Yates, Egeland, & Sroufe, 2003), and among older children, in terms of aspects of school-based functioning such as good academic performance and positive relationships with classmates and teachers (Masten & Coatsworth, 1998; Wyman et al., 1999).

In addition to being developmentally appropriate, indicators used to define positive adaptation must be conceptu-

ally of high relevance to the risk examined in terms of domains assessed and stringency of criteria used (Luthar, 1993). When communities carry many risks for antisocial problems, for example, it makes sense to assess the degree to which children are able to maintain socially conforming behaviors (Seidman & Pedersen, 2003), whereas among children of depressed parents, the absence of depressive diagnoses would be of special significance (Beardslee, 2002; Hammen, 2003). With regard to stringency of criteria, similarly, decisions must depend on the seriousness of the risks under consideration. In studying children facing major traumas, it is entirely appropriate to define risk evasion simply in terms of the absence of serious psychopathology rather than superiority or excellence in everyday adaptation (Masten & Powell, 2003).

Whereas approaches to measuring risk can involve one or multiple negative circumstances, *competence* must necessarily be defined across multiple spheres, for overly narrow definitions can convey a misleading picture of success in the face of adversity. Adolescents, for example, might be viewed very positively by their peers but, at the same time, perform poorly academically or even demonstrate conduct disturbances (Luthar & Burack, 2000; O'Donnell, Schwab-Stone, & Mueeed, 2002). Statistical examination of different outcome domains can, again, be done via various strategies. In variable-based analyses such as regressions, some researchers have simply examined each one in separate analyses, for example, predicting to scores on school achievement, peer acceptance, and emotional well-being (Zucker et al., 2003). An alternative approach, parallel to that previously described for cumulative risk scores, is to standardize scores across different adjustment domains and then add these to gauge overall competence across multiple spheres (Bolger & Patterson, 2003).

An innovative approach to defining competence is seen in research by Kim-Cohen, Moffitt, Caspi, and Taylor (2004), who statistically computed competence scores that were better than what would be expected given the presence of risk. In their sample of largely low-income children, these authors assessed several dimensions of risk: socioeconomic disadvantages, housing problems, and mothers' perceptions of economic deprivation. Multiple regression analyses were used with the three scores of deprivation predicting to two outcomes—conduct problems and intelligence scores—and the residuals from these analyses were standardized and saved. These residual scores represented, for each child, the difference between what would be expected given the level of risk, and what was actually observed (see also Elder & Conger, 2000). The investigators therefore arrived at two scores, behavioral resilience

and cognitive resilience (residuals of low conduct and high intelligence scores, respectively), and these were used as outcome variables in statistical analyses.

It should be noted that in some situations, competence is most appropriately operationalized in terms of “better than expected” functioning of families or communities rather than of the children themselves. As Seifer (2003) has argued, infants and even toddlers are still too young to reliably be judged as manifesting resilience because their functioning is so integrally regulated by others. At these young ages, therefore, it may be more logical to operationalize positive adjustment in terms of the mother-child dyad or family unit. In a similar vein, the label resilience can be most appropriate for communities of well-functioning at-risk youth. Research on neighborhoods, for example, has demonstrated that some low-income urban neighborhoods reflect far higher levels of cohesiveness, organization, and social efficacy than others (Leventhal & Brooks-Gunn, 2000; Sampson, Raudenbush, & Earls, 1997), with the potential, therefore, to serve as important buffers against negative socializing influences.

Vulnerability and Protective Processes

The central objective of resilience researchers is to identify *vulnerability* and *protective factors* that might *modify* the negative effects of adverse life circumstances, and, having accomplished this, to identify *mechanisms* or *processes* that might underlie associations found (Luthar & Cicchetti, 2000; Masten, 2001; Rutter, 2000, 2003). Vulnerability factors or markers encompass those indices that exacerbate the negative effects of the risk condition. Among youth living in the ecology of urban poverty, for example, male gender can be a vulnerability marker, for boys are typically more reactive than girls to negative community influences (see Luthar, 1999; Spencer, 1999). For children experiencing severe and chronic life adversities, those with low intelligence are more vulnerable to adjustment difficulties over time than are those with higher intelligence (Masten, 2001). Protective factors are those that modify the effects of risk in a positive direction. Examples include an internal locus of control and having a positive relationship with at least one adult; in groups of youngsters exposed to significant adversities, those with such attributes frequently fare better than youth who lack them (Luthar & Zigler, 1991; Masten, 2001; Rutter, 1999; Werner & Smith, 1992).

In the literature on resilience, discussions on the notions of vulnerability and protection have reflected considerable confusion around definition, measurement, and interpretation of statistical findings. As these processes form the

crux of what resilience researchers are interested in, salient issues in this regard are addressed individually in discussions that follow.

Identifying Protective and Vulnerability Factors: Variable-Based Approaches

In the resilience literature, there have been two major approaches to identifying protective or vulnerability factors, the first involving variable-based statistical analyses such as multivariate regressions. One of the first empirical efforts to use this approach was the previously mentioned groundbreaking paper by Garmezy et al. (1984). In this research, risk was considered on a continuous scale of cumulative life stress scores, and competence was defined in terms of three dimensions: good school grades and two dimensions of classroom behavior as rated by both classmates and teachers, engaged-disengaged and classroom disruptiveness. Hypothesized protective factors included the child's female sex, high intelligence, and high socioeconomic status (SES). These were examined not only in terms of direct links with competence outcomes (main effects) but also in interaction with stress (to determine if they might benefit children at high stress more than those at low stress). Hierarchical multiple regressions were performed, which showed significant main effect links for all hypothesized protective factors as well as a significant $IQ \times$ stress interaction effect (Garmezy et al., 1984). Thus, high SES, female sex, and high IQ were each advantageous for children with high life stress as well as those at low stress. The lone interaction effect showed that high IQ children maintained a generally high level of competence regardless of stress levels, whereas low IQ youth did far more poorly at high than low stress.

Garmezy and colleagues (1984) initially used the terms "compensatory" to describe their main effect findings and "protective" to describe the interaction effect they found, but other researchers have commonly used protective to refer to main effect links as well. In two other major programs of research, Werner's (Werner & Smith, 1982) study in Hawaii and Cowen, Wyman, and colleagues' Rochester Child Resilience Project (Cowen et al., 1996; Wyman et al., 1999), protective factors were simply those that distinguished between high-risk children who did well and those who did poorly (what this variable did or did not do for low-risk youth was not relevant). Given this differential use of the term, there were increasing exhortations for researchers to enhance specificity in how they referred to interactive effects (e.g., Luthar et al., 2000a; Luthar & Zelazo, 2003), with terms such as "protective-stabilizing" for trends such as those in the Garmezy et al. study and

"protective-enhancing," when at-risk children with the attribute performed much better than all others. Encouragingly, researchers are in fact using more differentiated terms in describing interactive effects (e.g., Brody, Dorsey, Forehand, & Armistead, 2002; Gerard & Buehler, 2004; Hammack, Richards, Luo, Edlynn, & Roy, 2004); despite some continuing variations in the labels used, there is a growing convention of clearly specifying what exactly the terms resilience, risk, vulnerability, and protection signify as operationally defined in particular studies.

Person-Based Analyses

Person-based analyses in resilience research essentially involve comparisons between a group of children who experience high risk and show high competence—a manifestly resilient group—and others varying on these two dimensions. Of particular interest are comparisons with youth at high risk and low competence, as these can illuminate factors that might confer protection against adversity. Comparisons with low risk and high competence groups, conversely, are particularly useful in determining whether the high competence of manifestly resilient children is actually commensurate with the levels shown by youth with relatively benign life circumstances.

Demarcating groups of manifestly resilient children is a little more complicated when there are multiple aspects of competence involved, as is the preferred approach; two strategies have been used in such instances (see Luthar & Zelazo, 2003). One involves standardizing and adding the scores across the different dimensions to obtain an overall competence score, and then allotting children to groups based on distribution of these composites. An advantage of this approach is that it takes into account where exactly people fall on the continuum of scores across various outcomes, so that a person extremely high on multiple domains of everyday competence, for example, would fall well above the sample mean on the composite score, even if he or she had significant problems in one particular symptom domain. The alternative strategy is to stipulate cutoffs that represent positive and negative adjustment on each indicator and designate children into different groups depending on where they fall across all of these, that is, in terms of competence scores that are above the sample mean and symptom levels that are below clinically significant levels. The subgroup of children who meet these success criteria across all indices is identified, and these children—again, ostensibly resilient—are compared with others who do not meet these criteria.

In the recent past, researchers have begun to use both variable- and person-based approaches in their analyses of

multiple competence domains. Buckner, Mezzacappa, and Beardslee (2003), for instance, conducted a study with 155 children from very low-income families and considered five different competence outcomes: a global rating of overall adaptive functioning and one of behavioral competence, and symptom levels on externalizing behaviors, depression, and anxiety. For their variable-based analyses, these authors derived a continuum of adaptation scores by converting into z-scores values on all five dimensions, adding these, and then computing an average. Hierarchical regressions were then conducted, with the hypothesized protective factors predicting to the continuous adaptation scores. In person-based analyses, the authors identified a subgroup of manifestly resilient children ($n = 45$) who had better than average adaptation and competence scores and symptom levels below clinically significant levels on all three domains. Nonresilient children ($n = 70$) were those who had at least one elevated symptom measure as well as global adjustment scores that fell below the very good range (40 children did not fit in either group). Again, the manifestly resilient youth were compared with others on the hypothesized protective factors.

Whereas person-based analyses have commonly been used to compare resilient and nonresilient groups, as in the preceding example, another useful application in resilience research, and one less often explored, is to ascertain conditional effects of influences as an alternative to using interaction terms. The latter strategy is exemplified in Seidman and Pedersen's (2003) work with low-income adolescents. These authors hypothesized that the benefits of adolescents' engagement in particular extracurricular domains—peer relations, academics, athletics, religion, employment, and culture—would depend on whether they were simultaneously invested in other activities as well. Cluster analyses yielded nine distinct groups of youth with varying profiles of activity involvement. Two clusters represented “pan-competence”: high engagement and high quality across most domains. Others included children high in one domain but low in others, such as the “academically disengaged athletes” (high in athletics but very low in academics). Cluster comparisons showed that the benefits of engagement in any one domain did in fact depend on engagement in the others: Youth with positive experiences in two or more domains showed significantly better adjustment than those with high-quality engagement in only one domain. To have examined the conditional links via variable-based analyses would have necessitated an impossibly high number of interaction terms (i.e., different combinations of seven engagement domains). In future resilience research, person-based analyses such as these carry much

promise for exploring the implications of different combinations of vulnerability and protective influences in individuals' lives.

Longitudinal Analyses: Resilience as “Bouncing Back”

Much of resilience research has involved identification of factors that correlate with relatively positive outcomes among at-risk youth, but in some instances, the approach has been to see what determines who will “bounce back” from earlier dysfunction (e.g., Ackerman, Brown, & Izard, 2003; Sroufe, Egeland, & Kreutzer, 1990). Long-term prospective studies are critical in illuminating turning points not only in childhood but across the life span, and at this time, data are available from a growing number of studies. Exemplary in this regard is Emmy Werner's (Werner & Smith, 2001) study of children in Hawaii followed from infancy through their 40s. Also spanning multiple decades is Laub and Sampson's (2003) follow-up of the Glueck and Glueck (1950) sample of low-income delinquent boys, originally assessed when they were 10 to 17 years old and most recently in their 60s, as well as George Vaillant's (Vaillant & Davis, 2000) parallel follow-up of the nondelinquent (but also low-income) comparison group. Hauser and Allen (Allen & Hauser, 1996; Hauser, 1999), similarly, have followed a group of psychiatrically hospitalized adolescents well into their adult years. Outside of the United States, critical longitudinal studies, all still ongoing, include the Isle of Wight study in England, where a 2-year-old birth cohort was followed to the age of 44 to 45 years (Collinshaw, Maughan, Pickles, Messer, & Rutter, 2004), the Dunedin Multidisciplinary Health and Development Study in New Zealand, where a cohort of 1,037 children were assessed through age 26 years (Moffitt, Caspi, Rutter, & Silva, 2001), and the Christchurch Health and Development Study, also in New Zealand, involving an unselected birth cohort of 1,265 children followed until the age of 21 years (Fergusson & Horwood, 2003).

Increasingly used in prospective studies are newer analytic techniques such as hierarchical linear modeling (HLM; Bryk & Raudenbush, 1987, 1992). HLM has the advantage of being able to accommodate data with some missing data points in different assessments over time and uneven time gaps between assessment points. Traditional methods such as multivariate repeated measures of analyses of variance require complete data for all subjects across all points of assessment as well as equal intervals between all points. Guttman et al. (2003) demonstrate the effective use of HLM in resilience research, showing academic trajectories between grades 1 through 12 among youth who

had been at high versus low levels of risk when they were assessed at the age of 4 years.

Another useful approach is that developed by Nagin and colleagues (Jones, Nagin, & Roeder, 2001; Nagin, 1999), which allows examination of different growth trajectories within a given group. Even when study samples consist of individuals who are similar on broad demographic indices, their growth trajectories over time can show some heterogeneity, and Nagin's procedure enables identification of disparate subgroups of individuals who each show the same distinct trajectories (e.g., those who increase, decrease, or remain stable on symptom or competence indices). Other advantages of this approach are that it can be used with both continuous and frequency data, and it allows for determination of links between different vulnerability or protective indices on the one hand, with diverse trajectories of maladjustment on the other (where harsh parenting, for example, is highly represented in trajectories of high stable or sharply increasing psychopathology, but not in others; see Latendresse & Luthar, 2005).

Interpretation of Findings on Risk Modifiers: Common Questions, Concerns, and Solutions

In variable-based analyses, a complication of interpretation has to do with whether significant main effect associations imply that low levels of the hypothesized asset imply unusually poor adjustment, or that high levels imply excellence in functioning, or both. There are, admittedly, a few "pure" vulnerability indices that can only create disorder when present but not excellence when absent, such as child maltreatment, whereas others can be beneficial when present without conferring vulnerability when absent, such as artistic or musical talents (Rutter, 2003). Many, if not most, indices, however, are bipolar in nature, with the potential for effects at both extremes (Masten, 2001). To illustrate, a significant main effect for extraversion among high-risk youth could imply either that high levels lead to exceptional competence (protection), or that low levels lead to unusual maladjustment (vulnerability).

Although researchers have often used these terms interchangeably, choosing somewhat arbitrarily between labels of vulnerability or protection for such bipolar variables, it can be useful to examine the distribution of scores to guide choices in this regard (Luthar & Zelazo, 2003). To continue with the same example, this could be done by demarcating, for interpretive purposes, a group high on extraversion (e.g., as defined by the top tertile) and one with low extraversion. Depending on the degree to which the mean competence scores of the low and high extraversion groups each deviate from the sample mean, this could illuminate

whether low extraversion connoted significant vulnerability (with competence scores much poorer than average), or whether high extraversion reflected protection (with competence well above the sample average). If both points deviated equally from the mean, the terms protection and vulnerability could in fact be used interchangeably. This type of scrutiny of mean competence scores—associated with high and low levels of the hypothesized risk modifier—can be useful not only in clarifying the nature of linear links, but also in detecting curvilinear links, where extraversion, for instance, is most adaptive at moderate levels with very high and low levels each being maladaptive. Use of this strategy is exemplified in Luthar and Latendresse's (2005b) study on the risk-modifying potential of different family processes (see also Stouthamer-Loeber et al., 1993).

Although there has been some confusion surrounding main effect findings, there has been a great deal more confusion around interaction effects; these have often been viewed as being at the crux of research on resilience, sometimes inappropriately emphasized as more important for inferring protection than direct, main effects (Luthar et al., 2000a, 2000b). It is certainly true that in the now classic papers of Garmezy et al. (1984) and Rutter (1987), protective effects were, in fact, defined in terms of interactions. On the other hand, neither of these scholars was dismissive of main effect findings. In point of fact, soon after publication of the 1984 Project Competence paper discussed earlier, Masten and Garmezy (1985, p. 14) defined protective factors as representing "a broader term. . . . [They are generally] associated with a lower than expected incidence of negative outcome, or, to take the more appropriate positive perspective, these factors are associated with better than expected outcomes." In another paper, Garmezy (1987, p. 170) characterized early main effect findings from Project Competence for both SES and IQ as being "protective factors against disruptive-aggressive responses to stress." None of these statements implies that factors cannot be "protective" unless they are in statistical interaction terms.

Over 2 decades ago, Rutter (1983) warned against an inappropriately high emphasis on statistical interactions because they are confused with interactions between the *person* and the environment. Discussing this problem in some depth, he noted that

personal interactions are not synonymous with statistical interaction effects. Most of the (person-environment) interactions that I have considered would not be detectable in terms of the conventional testing for multiplicative interactions in multivariate analyses. . . . [Further,] because interactions can take many forms and cannot be examined satisfactorily

through any one overall multivariate analysis, there is a considerable danger that spurious interactions will be detected as a consequence of looking at the data in numerous alternative combinations and permutations. (p. 315)

Similarly, in discussing interactional models, Masten and Garmezy (1985, pp. 36–37) underscored the importance of transactional perspectives, which involve “recognition that adaptation is an ongoing process of interactions between the systems of individual, family, social network, community, and society.” At the same time, these authors warned against an overreliance on multiple interaction terms to detect meaningful ways in which individual attributes transact with aspects of the environment to affect adjustment outcomes.

Aside from the fact that they typically have small effect sizes and thus are hard to detect, another concern about using interaction terms is that considering them might constrain detection of important *main effect* links. In contemporary studies involving analyses like those of Garmezy et al. (1984), it is not uncommon to see five or more protective factors explored in a given sample. When these variables are all considered as main effects, along with each of them in interaction with risk (as well as controls for demographics such as age, ethnicity, or gender), the resultant loss of statistical power, due to use of a large number of variables, renders Type III errors quite likely, with the potential of failing to detect main effect links that do actually exist. Unless researchers have specific a priori hypotheses predicting particular patterns of links between hypothesized risk modifiers and outcomes, therefore, it may be more prudent to omit them.

This suggestion is resonant with increasingly heard suggestions (García Coll, Akerman, & Cicchetti, 2000; García Coll et al., 1996; Hobfoll, Ritter, Lavin, Hulsizer, & Cameron, 1995; Luthar, 1999; Tucker & Herman, 2002) that in working with groups who have been little studied so far, as many at-risk groups are, it is best to focus intensively on how different processes operate *within* that sample, rather than seeking to document how they compare with patterns in other mainstream (or low-risk) groups. To be sure, many forces will show similar patterns—maltreatment hurts all children, as good parenting benefits all—but there are also several forces that are highly salient in some contexts but not others (Wyman, 2003). Experiences of discrimination, for example, are potent negative forces for minority children (García Coll et al., 1996; Szalacha et al., 2003) but do not apply to Caucasians. Optimism is related to life satisfaction and low depression among Caucasians but not among Asians (E. C. Chang, 2001). In other in-

stances, processes may actually reflect diametrically opposed patterns in different samples. Parental strictness is generally seen as detrimental for mainstream children but often benefits inner-city teens (Cauce, Stewart, Rodriguez, Cochran, & Ginzler, 2003; Sameroff et al., 2003). In cases such as these, it would likely be a mistake for researchers to explore main and interaction effects with high- and low-risk samples combined. Nonsignificant main effect associations may well be found—with opposing direction of links in the two samples canceling each other out—and interaction effects also statistically nonsignificant, given their instability and small effect sizes.

As resilience researchers consider using or not using interaction terms to assess samples including both high-risk and comparison groups, therefore, it is critical that they carefully consider the substantive questions of interest. What within-group multivariate analyses of at-risk samples illuminate is the *relative significance of particular protective process*, for example, school safety or neighborhood patrolling, vis-à-vis other influences in the same population. Knowledge such as this can be far more useful, conceptually and practically (in prioritizing intervention themes), than is evidence that a particular set of links is statistically stronger or weaker than parallel associations in a low-risk group. Even if a researcher's goals were to examine the generalizability of processes identified among youth facing high adversity, this could easily be accomplished with separate analyses of the comparison group (by contrasting of beta weights in regressions, if necessary, to determine whether links differ significantly in strength). In sum, within-group analyses are often the strategy of choice when seeking to learn about intervention priorities in subgroups of the population about whom we currently understand little. The conceptual appeal of interaction effects must not obscure the fact that including multiple interaction terms for “exploratory” purposes can sacrifice much in terms of statistical power, possibly reducing the likelihood of detecting main effects that do exist in reality.

A final cautionary note regarding the joint consideration of high- and low-risk groups is the potential for spurious findings on protection. In other words, statistically significant main effect terms might be erroneously labeled as compensatory or protective against risk even when the effects occur only in the *low-risk* group (Luthar & Goldstein, 2004). To illustrate, a series of studies on children varying in level of violence exposure showed significant overall links with competence for various positive family variables, such as high family support and high levels of monitoring (Hammack et al., 2004; Kliewer et al., 2004; Sullivan, Kung, & Farrell, 2004). More in-depth analyses,

however, revealed that in many cases, the family assets were helpful only among children with low exposure to community violence. Among children whose scores were at the higher end of the violence exposure measures, the benefits of variables such as family support were essentially negligible (Luthar & Goldstein, 2004). For circumstances such as these, Sameroff and colleagues (Gutman et al., 2003; Sameroff et al., 2003) have argued that terms such as “promotive”—which do not imply that any benefits are conferred at high-risk levels—are more appropriate than is “protective.” Other terms that avoid implying effects at high risk include “beneficial” and “salutary” (Luthar & Zelazo, 2003); researchers could also simply refer to the attributes as “assets” (Masten & Powell, 2003).

Understanding Underlying Processes

A hallmark of the current generation of resilience research is attention to process: If studies are truly to be informative to interventions, they must move beyond simply identifying variables linked with competence to explain the specific underlying processes (Cowen et al., 1996; Luthar & Cicchetti, 2000; Masten, 2001; Rutter, 2000, 2003; Werner & Johnson, 1999; Wyman et al., 1999). This need to “unravel” underlying mechanisms applies to the risk condition itself as well as to hypothesized protective and vulnerability indices. With regard to risk transmission, for example, maternal depression can affect children through various environmental processes, including conflict between parents, stressful events in the family, children’s modeling of ineffective coping styles, and negative parenting behaviors (Hammen, 2003); biological processes such as diffuse reductions in cortical activation or generally lowered left frontal activation, may also be implicated (see Dawson et al., 2003). Similarly, the negative effects of maternal drug abuse on children may derive from various problems that tend to co-occur with women’s addiction, such as depressive and anxiety disorders and high life stress, as much as or more than from the drug abuse per se (Luthar, D’Avanzo, & Hites, 2003). Disaggregating or unpacking the relative contributions of each of these family processes is critical not only for theory and research, but also for designing interventions.

Although many global sociodemographic and psychological constructs (such as family SES and parents’ mental illness) are commonly thought of as connoting high versus low risk, attention to processes has sometimes led to findings belying commonplace assumptions. To consider family SES, for example, material wealth is generally viewed as

connoting low risk. However, an accumulating body of literature indicates that (1) among adults, high preoccupation with wealth and status may often compromise well-being (see Kasser, 2002), and (2) children of the wealthy and well-educated can show elevated maladjustment in some domains, particularly substance use and internalizing symptoms, possibly as a result of high achievement pressures and isolation from parents (Luthar, 2003; Luthar & Latendresse, 2005a; Luthar & Sexton, 2004). Findings such as these support what elders in developmental psychology cautioned us about decades ago: Global indicators of children’s “social addresses” are limited in what they can tell us about children’s family lives (Bronfenbrenner, 1986; Zigler, Lamb, & Child, 1982). In trying to illuminate who is at risk and why, we need direct attention to the processes that actually exist within their families.

Turning to mechanisms underlying protective and vulnerability factors, examples of possibilities in this regard are seen in Criss and colleagues’ (Criss, Pettit, Bates, Dodge, & Lapp, 2002) descriptions of various processes via which peer acceptance might confer advantages for children with disturbed family functioning. When parents are highly stressed, good peer relationships can provide alternative ways to meet needs for connectedness or concrete help. They may also serve to modify inappropriate child behaviors, such as aggression, that distressed parents cannot discipline adequately. Indirect effects on adults may also be involved; children’s peer relationships may lead their parents to network with the other children’s parents, which in turn may confer benefits such as illuminating new approaches to discipline. Finally, positive peer relations in the school context may promote bonding with school and teachers.

With regard to vulnerability factors, an example of diverse underlying mechanisms is seen in research on hostile, coercive family environments (e.g., Compton, Snyder, Schrepferman, Bank, & Shortt, 2003). These are likely to exacerbate further the vulnerability of children in high-risk groups via various conduits, including ineffective parenting, unresolved conflict and discord, insufficient child monitoring and supervision, and lack of close relationships with one or both parents (Rutter, 2000).

Moving beyond Psychological Processes: The Importance of Biology and Interdisciplinary Work

The preceding examples—like most of resilience research thus far—generally encompass psychological variables; there is a critical need for scientists to increase consideration also of biological indices, again, both as mediators of

risk itself and as processes underlying vulnerability and protective factors (Cicchetti, 2003; Rutter, 2002b). In a seminal overview paper, Curtis and Cicchetti (2003) have explained the importance of diverse biological processes ranging from neuroendocrinology to capacities to regulate emotions. Modern neuroscience, for example, has established the phenomenon of neural plasticity, where there is structural and functional reorganization of the brain in response to environmental inputs. These physical changes in the brain, in turn, can have substantive implications in determining vulnerability and protective processes to future psychopathology (Curtis & Nelson, 2003). Evidence such as this points to several issues worthy of investigation by future resilience researchers, such as whether stressful or challenging tasks might evoke activation in different areas of the brain (e.g., as assessed by functional magnetic resonance imaging) among competent and noncompetent performers, or whether resilient and nonresilient children, matched on adversity type and level, might show differing patterns of brain structure and functioning.

In terms of protective processes, the capacity to regulate or modulate negative emotions in the face of threats is of obvious importance for managing well in the face of threat (e.g., Aspinwall & Taylor, 1997; Buckner et al., 2003; Eisenberg, Champion, & Ma, 2004), and here again, biological processes can be salient. Various environmental influences likely affect whether individuals become adept or inept at regulating their emotions, such as significant adults' responses to and tolerance of displays of negative affect in the early childhood years. However, at least three biological processes might also be implicated. The first is the capacity to recover relatively quickly from negative events experienced (Davidson, 2000). Such "rapid recovery" tendencies can be gauged by studying the startle reflex, which is an involuntary response (a fast twitch of facial and body muscles) to a sudden and intense visual, tactile, or acoustic stimulus. Studies have shown that adverse environmental influences affect not only the startle reflex, but also the neural network that underlies this response (Curtis & Cicchetti, 2003).

A second aspect of brain functioning that might affect emotion regulation, according to Curtis and Cicchetti (2003), is hemispheric electroencephalograph (EEG) activity. In general, the right hemisphere participates more heavily in negative affect and the left hemisphere more in positive emotion. Individuals who show relatively high activation of the left prefrontal cortex have been found to report more positive affect both when at rest and in response to positive stimuli, and also show less negative emotion in

responding to negative stimuli (Sutton & Davidson, 1997; Wheeler, Davidson, & Tomarken, 1993). Thus, asymmetry in brain functioning might be implicated in differing capacities to regulate emotions.

A third biological mechanism that might be implicated is neuroendocrinal in nature. Chronic exposure to stressful experiences tends to lead to excessive activation of the hypothalamic-pituitary-adrenal (HPA) axis and the resultant elevation of the stress hormone cortisol. Hypercortisolism in turn can cause damaging and sometimes pathogenic effects on neurons (McEwen & Sapolsky, 1995; Sapolsky, 2000) and can also affect the synthesis and reuptake of neurotransmitters as well as the density of sensitivity of receptors (McEwen, 1994; Watson & Gametchu, 1999). Again, these findings point to the possibility that resilient individuals are those who, in the face of various stressors, tend to return relatively quickly to baseline levels of neuroendocrine functioning and thus avoid the damage conferred by hypercortisolism.

Aside from the aforementioned categories, another important set of biological processes are those involving genetic influences. Noteworthy in this regard are works of Rutter, Caspi, and their colleagues (Caspi et al., 2003; Kim-Cohen et al., 2004; Rutter, 2003) on genetic factors potentially involved in resilience. Discussed at some length in the next section of this chapter (under "Family-Level Processes"), recent studies have identified G-E interactions—wherein both genes and child-specific environmental influences contribute to behavioral resilience—as well as specific gene markers that contribute to protection or vulnerability in the face of childhood adversities.

In the years ahead, it is imperative that resilience researchers begin to pay concerted attention to biological processes such as these, in addition to psychological ones. Thus far, the neglect of biology in this literature could be attributed to at least two factors: (1) The technology for assessing many of these processes is relatively new and complicated, and (2) most resilience researchers have little formal training in biological processes, and those who do have such training have not studied resilience (Curtis & Cicchetti, 2003). Admittedly, there are few who will develop skills and expertise across both of these realms, as is exemplified by Rutter (2002a, 2002b) and Cicchetti (2003), but interdisciplinary collaborations provide a viable route to bringing together both bodies of knowledge. Concerted movement toward such collaborations must be treated as an imperative for the continued vitality of the science of resilience in future years.

Another type of interdisciplinary collaboration that will be critical in moving the field of resilience forward is with qualitative researchers from fields such as anthropology. Ethnographic, qualitative research is critical, particularly in guiding our exploration of groups little studied thus far (Garcia Coll, 2005; Luthar, 1999). Being generative, inductive, and focused on *describing* salient processes in naturally occurring phenomena (LeCompte & Preissle, 1993), this type of research can provide critical directions for future quantitative studies (typically favored by psychologists) involving hypothesis testing of resilience processes. Put simply, meaningful hypothesis testing presupposes knowledge of the web of interrelated forces that can affect the phenomenon under study: "We must understand how persons within a culture or ethnic group symbolically construct concepts such as self and others before we can understand factors attributed to vulnerability and resilience" (Cohler et al., 1995, p. 781).

Ethnographic studies involving at-risk families have illuminated several potentially important processes that merit further scrutiny in verificative or predictive research on resilience (see Hauser, 1999). To illustrate, interviews with inner-city families led Burton and colleagues (Burton, Allison, & Obeidallah, 1995) to identify several aspects of adolescent adaptation, all rarely considered in psychological research, that might promote long-term resilience. These include contribution to cohesion at the family and the community level (e.g., helping elderly folk in the community) and development of creative talents in contextually relevant models (such as rapping or doing hair and nails well).

It should be noted, too, that qualitative research is particularly critical in trying to translate findings from basic research on vulnerability and protective processes into interventions. The importance of this is exemplified in work on benefit finding in the face of bereavement. In the aftermath of bereavement, it has been found that some individuals report some positive outcomes, such as feelings of having grown personally, developed new perspectives on life, and increased closeness in other relationships (Affleck, Tennen, & Rowe, 1991; Davis, Nolen-Hoeksema, & Larson, 1998). However, any intervention efforts to help people identify such benefits following bereavement can be counterproductive, perceived by the bereaved individuals as insensitive and personally offensive (Nolen-Hoeksema & Davis, 2002; Tennen & Affleck, 2002).

In addition to the biological and qualitative literatures, evidence on clinical interventions also subsumes potentially valuable lessons on processes in resilience. Examples are seen in studies of the companionship provided by pets as well as therapeutic properties of music and art. With re-

gard to the former, almost 2 decades ago, the National Institutes of Health (NIH; 1988) convened the NIH Technology Assessment Workshop on the Health Benefits of Pets, as research had demonstrated that pet owners experienced increased 1-year survival after discharge from a coronary care unit (Friedmann, Katcher, Lynch, & Thomas, 1980). A decade later, scientific papers reported that pet owners had slightly lower systolic blood pressure, plasma cholesterol, and triglyceride values than non-pet owners (Anderson, Reid, & Jennings, 1992) and that dog ownership was associated with an increased likelihood of 1-year survival after a myocardial infarction (Friedmann & Thomas, 1995). Findings on pet ownership were seen as operating through the reduction of psychosocial risk factors (Patronek & Glickman, 1993), and the final report of the NIH Technology Assessment Workshop proposed that future studies of human health should consider the nature of relationships with pets as significant variables (Beck & Glickman, 1987). A series of recent papers in the *American Behavioral Scientist* (e.g., Barker, Rogers, Turner, Karpf, & Suthers-McCabe, 2003; Beck & Katcher, 2003; Meadows, 2003) underscore the value of pursuing such research.

In a similar vein, therapeutic interventions suggest that creative self-expression warrants some attention by resilience researchers. In a meta-analysis published in the *Journal of Child Psychology and Psychiatry and Allied Disciplines*, Gold, Voracek, and Wigram (2004) included 11 studies on music therapy that resulted in a total of 188 subjects for analyses. Effect sizes from these studies were combined, with weighting for sample size, and their distribution was examined. Results showed that music therapy has a medium to large positive effect ($ES = .61$) on clinically relevant outcomes. The finding was statistically significant at $p < .001$ and statistically homogeneous, and no evidence of a publication bias was identified.

Resilience and Related Constructs

Aside from confusion about aspects of research on resilience itself, there also have been questions about whether it is truly a unique scientific construct or redundant with others. The reality is that there are in fact similarities but also some important differences. Of the psychological constructs with which resilience has some overlap, social competence is perhaps the most salient. The roots of this dimension lie in Havighurst's theory of developmental tasks, where social competence is defined as a track record of effective performance in developmental tasks that are salient for people of a given age, society or context, and historical time (Masten & Coatsworth, 1998).

As Masten (2001, p. 716) has noted, competence and resilience may be described as closely related subconstructs within the broader construct of adaptation; both constructs represent “doing okay.” Furthermore, both are relative terms, in that social competence is defined relative to what society expects of the average child, whereas resilience is defined relative to expectations of the average child given exposure to a particular risk (i.e., “better than expected functioning”). Finally, in themselves, the terms competence and resilience do not imply exceptional performance in any *specific* domain; rather, they allude to adjustment domains that are salient within a particular developmental and ecological context.

There are four major differences between the two concepts. First, resilience, but not competence, presupposes risk. Second, resilience encompasses both negative and positive adjustment indices (absence of disorder and presence of health), and competence chiefly the latter. Third, resilient outcomes are defined in terms of emotional and behavioral indices, whereas competence usually involves manifest, observable behaviors. Fourth, resilience is a superordinate construct that subsumes aspects of competence (along with high levels of risk).

A second overlapping construct—and one with which resilience is often confused—is *ego resiliency*, which is a trait reflecting general resourcefulness and sturdiness of character and flexibility of functioning in response to varying environmental circumstances (see Eisenberg, Spinrad, et al., 2004). Commonalities with resilience are that both involve strengths; illustrative descriptors of ego resiliency (Block, 1969) include “engaged with the world but not subservient to it” and “integrated performance under stress.” Differences are that (1) only resilience presupposes conditions of risk, and (2) resilience is a phenomenon, not a personality trait. Finally, just as competence is subsumed within resilience, ego resiliency has been examined as a potential predictor, that is, a personality trait that may protect individuals against stressful experiences (Cicchetti & Rogosch, 1997).

Hardiness is a construct in the adult literature that shares some attributes with resilience—it, too, presupposes risk—but also with ego resiliency; it refers to a specific set of traits in the individual rather than the combination of risk plus competence, as does resilience. Proposed by Kobasa and colleagues (Kobasa, Maddi, & Kahn, 1982) to account for individual differences in responses to life stressors, hardiness is defined as the presence of three personality dispositions: commitment (feeling connected, having a purpose, being active, etc.), control (feelings of being able to control what happens in one’s environment),

and challenge (welcoming change instead of perceiving it as disruptive).

Resilience and Related Disciplines

As the construct of resilience has some features overlapping with others, such as competence and hardiness, the scientific study of resilience has much in common with other disciplines in terms of central research questions and the constructs and samples assessed; similarities are most pronounced with risk research, prevention science, applied psychology, and positive psychology. Considering *risk research* to begin with, there are more similarities than differences, which is not surprising as resilience research grew out of the risk paradigm (Luthar & Zelazo, 2003). In both these traditions, researchers are concerned with children who face notable life adversities, seeking to understand the types of forces that might lead to variability in adjustment outcomes. A major point of difference, however, is that resilience researchers are explicitly concerned with positive forces as well as negative ones—assets as well as deficits in both socializing forces and child outcomes—whereas risk research is focused primarily on negative forces.

A second difference is that studies of resilience entail concerted attention to process. At the core of both risk and resilience research is the common goal of identifying correlates of adjustment among children at risk, but for resilience researchers, this represents but a fraction of the overall task. As noted earlier, once statistically significant associations are found, there must be an in-depth scrutiny of processes that might underlie statistical links with an eye toward informing future interventions.

Similar distinctions apply with *prevention science* as traditionally defined, although in current conceptualizations, differences are much smaller, pertaining less to substantive areas of interest than to the degree of attention to the development and implementation of programs. Prevention science has long been seen as having as its core objective the reduction of disorder or disease among individuals at risk and not the promotion of health or competence (see Munoz, Mrazek, & Haggerty, 1996). In resilience research, there is explicit consideration of maximization of positive outcomes as well as the minimization of pathology or disease (Luthar et al., 2000b). However, several senior scientists have sought to broaden the scope of the prevention discipline to include positive outcomes as well (Cowen & Durlak, 2000; Elias, 1995; Weissberg & Greenberg, 1998), arguing that efforts to reduce problems are most effective when coordinated

with explicit attempts to also foster competence (Weissberg, Kumpfer, & Seligman, 2003). In point of fact, the terms prevention and resilience coexisted in a task force, Seligman's American Psychological Association Presidential Task Force on Prevention: Promoting Strength, Resilience, and Health in Young People (Weissberg et al., 2003). Thus, at this time, the only minor difference between the fields of resilience and prevention is that the former is focused equally on basic and applied research, whereas the latter is more strongly focused on applications of research findings in programs for youth and families.

Applied developmental science (ADS) is a relatively new discipline, which is defined as "scholarship that seeks to advance the integration of developmental research with actions—policies and programs—that promote positive development and/or enhance the life chances of vulnerable children and families" (Lerner, Fisher, & Weinberg, 2000). ADS and the study of resilience are, again, highly overlapping: Both involve a focus on children and families at risk, on positive outcomes and assets among them, on normative and atypical developmental processes as they emerge in different cultural settings, and on interventions and policies to promote positive development. In both instances, furthermore, there is a strong emphasis on collaborations between universities and communities to ensure the relevance of research activities and components of interventions and policies to the needs and values of people in that community (Luthar & Cicchetti, 2000). A minor point of difference is that ADS places somewhat more emphasis on outreach interventions conducted under real-world circumstances and constraints, whereas resilience research more equally emphasizes such efforts and the more traditional laboratory-based clinical trials, which allow for more stringent documentation and evaluation even though they are conducted under highly controlled, contrived conditions that cannot be replicated in the real world (Lerner et al., 2000; Weisz, Hawley, Pilkonis, Woody, & Follette, 2000).

Also closely related is the applied science of *early childhood intervention*. Major points of emphasis in this discipline are the interchange between biology and experience, on cultural variations in child-rearing beliefs and practices, on relationships as the building blocks of healthy development, on children's self-regulation as a critical capacity affecting all domains of behavior, and on the potential to shape human development by reducing risk and promoting protective influences. The construct of resilience is specifically mentioned among the core concepts guiding the science of early childhood intervention (Shon-

koff & Phillips, 2000). Again, the differences between this and the field of resilience are minor; early childhood interventions concern children up to 5 years of age and their families, whereas resilience research thus far has been focused as much on middle childhood and adolescence as on early childhood (if not more so). Furthermore, early childhood interventions have often been focused on cognition, intelligence, and language development and, in some instances, behavioral conformity; there is relatively little attention to mental health or psychiatric disturbances. Resilience research, by contrast, is concerned with psychological, emotional, social, and psychiatric outcomes among children and parents; cognition and language are not considered outcome domains.

Turning from developmentally based disciplines with a focus on children to one focused primarily on adults, resilience has features in common with *positive psychology*, also a relatively new field. Martin Seligman (2002, p. 3), who played a seminal role in the emergence of this discipline, defined it thus:

The field of positive psychology at the subjective level is about positive subjective experience: well-being and satisfaction (past); flow, joy, the sensual pleasures, and happiness (present); and constructive cognitions about the future—optimism, hope, and faith. At the individual level it is about positive personal traits—the capacity for love and vocation, courage, interpersonal skill, aesthetic sensibility, perseverance, forgiveness, originality, future-mindedness, high talent, and wisdom. At the group level it is about the civic virtues and the institutions that move individuals toward better citizenship: responsibility, nurturance, altruism, civility, moderation, tolerance, and work ethic.

Unlike the minor differences with the three fields previously discussed, there are several factors that set the field of resilience apart from positive psychology, the first of which concerns the presence of life adversities. As noted earlier, resilience research presupposes exposure to significant adversity, whereas positive psychology concerns all individuals, not just those who have experienced major risks.

The second difference concerns the presence of developmental issues. Emerging as a part of the discipline of developmental psychopathology, resilience research has involved concerted attention to developmental themes (Luthar & Cicchetti, 2000; Masten, 2001), with a focus generally on childhood and adolescence, but recently, on processes among adults as well (e.g., Bonnano, 2004; Collinshaw et al., 2004; Staudinger, Freund, Linden, & Maas, 1999; Vaillant & Davis, 2000). In positive psychol-

ogy research thus far, by contrast, developmental issues are not highlighted, and the focus is overwhelmingly on adults. In a chapter discussing children in the *Handbook of Positive Psychology* (Snyder & Lopez, 2002), the authors noted: “We strongly urge that positive psychology theorists and researchers consider a developmental perspective rather than focusing only on adults (and children as ‘smaller humans’) or giving minimal attention to development by considering childhood *only* as a period preceding adulthood” (Roberts, Brown, Johnson, & Reinke, 2002, p. 671).

The third difference pertains to operationalization of positive outcomes, and there are two issues relevant here. One is that, as its name suggests, positive psychology is concerned only with positive aspects of adjustment and health promotion and not with the evasion of mental illness. Resilience encompasses both poles. As noted earlier, positive adaptation is defined as the best possible outcomes that can be achieved given the risk experienced; in the face of severe trauma, risk evasion has—appropriately—been defined in terms of the avoidance of major psychiatric problems.

Another difference concerns the use of behavioral versus psychological dimensions to operationalize positive adaptation. Resilience researchers have strongly emphasized overt behavioral success as judged by others: “adaptive behaviors” as rated by teachers, classmates, friends, parents, or others. Whereas there is some effort to ascertain subjective feelings of unhappiness, there have been no attempts, to our knowledge, to ask children about their own subjective feelings of happiness (see also Roberts et al., 2002). And these are the constructs that form the very crux of positive psychology; interestingly, in this case, there do not seem to be efforts to ascertain *others’* opinions on whether the individual is “doing well,” as a good spouse or parent, for example, or a colleague at work. In fact, even when there are constructs tapping into interpersonal themes, these largely involve the individual’s own reports, with social acceptance defined in terms of *their* having positive attitudes toward others, and social integration as their feelings of being supported by their community (Keyes & Lopez, 2002).

The reasons for this differential emphasis are not entirely clear, although it could derive partly from the fact that much of the work on positive psychology has been done in Western countries, where individualism is highly emphasized. It is possible that in Eastern cultures with a strong emphasis on collectivism, positive psychology would be defined as much in terms of *others’* judgments of adults’ doing right by significant others (as resilience is

commonly described among children in contemporary research). This could be a direction usefully explored in future positive psychology research. By the same token, there is a need for childhood resilience researchers to consider not only the degree to which young people conform to adults’ expectations and evade personal psychopathology, but also the degree to which they themselves subjectively experience feelings of happiness.

Despite these areas of difference, it should be emphasized again that resilience research has many similarities to all the other disciplines considered here, and researchers in each of these traditions have much to learn from those in the others. The excessive splintering of psychology as a field has increasingly been deplored (e.g., Catalano, Hawkins, Berglund, Pollard, & Arthur, 2002; Sternberg & Grigorenko, 2001); to remain insulated from others’ research that clearly overlaps with one’s own is ill-advised. Encouragingly, there have been increasing efforts to bring together the major themes and ideas from these fields. Two recent compendia of articles (Sheldon & King, 2001; Snyder & Lopez, 2002) included, along with several articles on positive psychology among adults, papers on resilience in childhood (see Masten, 2001; Masten & Reed, 2002). More recently, in a book on children facing familial and community adversities (Luthar, 2003), senior investigators in the risk, resilience, and prevention science traditions came together, allowing a distillation of major findings across all of these disciplines. In future efforts, the choice of terms that each of us chooses to characterize our respective research efforts is, in essence, not substantively important (i.e., whether we call ourselves resilience researchers, prevention scientists, or applied developmental scientists). What is much more important is that we remain aware of the body of knowledge, highly relevant to our own research efforts, subsumed in the other literatures mentioned (Garcia Coll, 2005). In the pithy words of Shonkoff and Phillips (2000, p. 339), we must guard against “narrow parochial interests that invest more energy in the protection of professional turf than in serving the best interests of children and families.”

VULNERABILITY AND PROTECTIVE PROCESSES: SUMMARIZING EXTANT EVIDENCE

This section of the chapter encompasses major findings from almost half a decade of research on resilience. In describing the forces that might modify effects of high-risk

life circumstances, discussions are focused largely on research with children, as there are still relatively few studies of resilience among adults. Additionally, the effort is toward prioritization of different categories of risk modifiers. Resilience researchers have been criticized for producing lists of sundry protective and vulnerability factors (see Gorman-Smith & Tolan, 2003; Luthar et al., 2000a); although possibly comprehensive, such lists are of limited practical use because all itemized indicators (ranging from parents' intelligence, to neighborhood safety, to children's social skills) can never be addressed in a given intervention. From an intervention standpoint, what is needed is some type of prioritization of domains in terms of overall likelihood of yielding substantial benefits (Luthar & Zelazo, 2003).

Accordingly, organization of this section is based on the following considerations. In general, primacy in discussions is given to the most *influential* vulnerability and protective factors, that is, those whose effects are relatively enduring, robust, or hard to overcome by others. Second, more emphasis is placed on *modifiable modifiers*. Whereas intrinsic characteristics like gender and race certainly can affect outcomes, these are afforded less prominence than are those that are more amenable to change, such as parental discipline and teacher support.

Third, discussions focus, in sequence, on vulnerability and protective forces in the domains of the family, the community, and the children themselves. The family is not only the most proximal of children's external environments but also the most enduring; it therefore makes sense to focus on this first in the triad of factors (Luthar & Zelazo, 2003). The community, in turn, affects children both directly and indirectly through their parents, so that modifying aspects of the wider environment can have benefits through both routes. With regard to children's own attributes, these obviously do play a major role in resilient adaptation, but many child attributes (such as self-efficacy and even intelligence) are themselves shaped by forces in the environment. Accordingly, these are discussed third in the sequence (cf. Luthar & Zelazo, 2003).

Rather than describing findings of individual studies in the research literature, the emphasis in this section is on summarizing major themes that have emerged regarding salient vulnerability and protective processes, with a few investigations briefly described for illustrative purposes. Along with empirical evidence on the three sets of risk modifiers, relevant evidence from intervention efforts is also considered. As Cicchetti and Hinshaw (2002) have noted, basic research must inform interventions; at the same time, data from interventions can provide valuable

lessons for science by showing, for example, whether targeting hypothesized protective factors does in fact predicate resilient adaptation.

Family Relationships: Effects of Maltreatment

Of the many factors that affect the trajectories of at-risk individuals, among the most potent is maltreatment by primary caregivers. Maltreatment co-occurs with many high-risk circumstances, including parent mental illness, parental conflict, community violence, and poverty (Eckenrode et al., 2000; Lynch & Cicchetti, 1998), thus serving as a rampant vulnerability factor. Maltreated children show deficits spanning multiple domains; as Cicchetti (2002, p. 1416) has noted, "Child maltreatment exerts deleterious effects on cognitive, social, emotional, representational, and linguistic development, as well as disrupts the development of emotion regulation, secure attachment relationships, an autonomous and integrated self-system, effective peer relations, and the successful adaptation to school."

Even when positive profiles of adaptation are displayed among maltreated children, they tend to be unstable over time. In their longitudinal study of low-income children, Farber and Egeland (1987) found that, of 44 children identified as maltreated, *none* maintained competent functioning across the period from infancy to preschool. Cicchetti and Rogosch (1997) examined resilience in a sample of 213 maltreated and nonmaltreated low-income children. On a composite measure of adaptive functioning, only 9.8% of maltreated children were ever classified as high-functioning during any of the three annual assessments; fewer than 2% were classified as high-functioning across time. Similarly, Bolger and Patterson (2003) identified maltreated children who showed positive adjustment in at least one of four domains (peer acceptance, internalizing, externalizing, and academic achievement) without doing very poorly in any, and only 1 of the 107 maltreated children met these criteria across multiple assessments over time.

This degree of dysfunction is not surprising given that maltreatment connotes serious disturbances in the most proximal level of the child's ecology, with the caregiving environment failing to provide multiple expectable experiences essential for normal development (Cicchetti, 2002,). In maltreating families, parental care does not meet children's basic needs for physical sustenance and protection, emotional security, and social interaction. Parents interact with their children less than do others and display more negative affect to them. Anger and conflict are often pervasive, both between parents themselves and between the adults and the children, and the family system as a whole is

characterized by chaos and instability. Thus, it is unsurprising that the “social, biological, and psychological conditions that are associated with maltreatment set in motion a probabilistic path of epigenesis for maltreated children characterized by an increased likelihood of failure and disruption in the successful resolution of major stage-salient tasks of development” (Cicchetti, 2002, p. 1416).

Despite evidence that resilience is rare among maltreated children, profiles of adjustment are obviously not homogeneous, and the degree of diversity that is observed might rest largely on the heterogeneity of maltreatment experiences in terms of severity, pervasiveness, age at onset, or chronicity (Cicchetti & Rogosch, 1997). To illustrate, studies have shown that children experiencing maltreatment early in life and continuing into the adolescent years tend to show early onset, persistent behavior problems (such as conduct problems, substance use, and early sexual activity), and difficulties in different aspects of peer relationships (Aguilar, Sroufe, Egeland, & Carlson, 2000; Bolger & Patterson, 2003; Eckenrode et al., 2001).

Other forces that can make a difference include positive relationships with others (see Reis & Collins, 2004). As will be discussed later in this section, quality parenting is the single most robust of protective factors for children exposed to various adversities (Luthar & Zelazo, 2003; Masten & Coatsworth, 1998), so that positive relationships with alternative caregivers could serve protective functions for maltreated youth (although this has not yet been systematically examined, to our knowledge). The potential of other relationships is seen in Bolger and Patterson’s (2003) longitudinal data showing that friendship—though not a substitute for adult caregiving—may play a protective role. Among chronically maltreated children, having a positive, reciprocal friendship was associated with an increase over time in self-esteem, possibly due to a mediating process such as decreases in loneliness, increases in perceived acceptance, improved social skills, and changes in working models of attachment.

Personality factors may also make a difference. Cicchetti and Rogosch (1997) found that ego resiliency and ego control as well as positive self-esteem predicted relatively competent functioning in maltreated children, as Bolger and Patterson (2003) found that maltreated children with higher internal control had lower symptom levels than others. The mechanisms underlying such “protective child attributes” are discussed later in this section, but for the moment, a critical caveat bears explicit mention: The experience of maltreatment also compromises the very personal attributes that could serve protective functions (Bolger & Patterson, 2003). As Cicchetti (2002) notes, maltreated

children as a group show many deficits in emotional regulation, either showing excessive amounts of negative affect or blunted affect with little positive or negative emotion. As a result of difficulty in effectively modulating physiological arousal, they also have trouble coping with emotionally stressful situations. In other words, the repeated developmental disruptions of a maltreating environment not only directly increase risk for maladjustment, but tend to work against positive personal attributes that could have served protective functions.

Protective Family Forces: Attachment, Nurturance, and Support

Whereas chronic maltreatment is pernicious, child abuse is obviously not inevitable among parents facing major life adversities, and positive family relationships can do much to promote resilience in children faced with challenging circumstances (Conger & Conger, 2002; Elder & Conger, 2000). The critical importance of strong family relationships has been emphasized by child development theorists from diverse perspectives. This theme is at the core of classic psychodynamic perspectives ranging from Bowlby’s (1988) attachment theory and the Eriksonian emphasis on trust versus mistrust (Erikson, 1993), to Freud’s (Freud & Gay, 1995) stages of psychosexual development and Mahler’s (1986) notion of human symbiosis. Outside of psychodynamic viewpoints, Havighurst’s (1948) earliest developmental tasks—learning to walk, talk, and distinguish right from wrong—presuppose the presence of an attentive adult to foster these, as learning theorists have long emphasized the role of parents’ reinforcement patterns as well as modeling particular behaviors to powerfully shape the child’s emerging personality (Bandura, 1977; B. F. Skinner, 1974).

Consistent with these theories of normative child development, strong family relationships have long been seen as critical in maintaining good adjustment in the face of adversities. The earliest studies of resilience indicated that the presence of a close relationship with at least one parent figure was highly protective across risks ranging from early institutionalization and serious parent mental illness, to chronic family poverty and multiple coexisting adversities (Anthony & Koupernik, 1974; Garmezy, 1974; Murphy & Moriarty, 1976; Rutter, 1979; Werner & Smith, 1977). Similarly, recent reviews of the existing literature continue to point to supportive and responsive parenting as being among the most robust predictors of resilient adaptation (Luthar & Zelazo, 2003; Masten, 2001; Rutter, 2000; Werner, 2000).

Particularly important in shaping long-term resilient trajectories are early family relationships. In their comprehensive review of the early childhood literature, Shonkoff and Phillips (2000, pp. 27–28) emphasized, “From the moment of conception to the finality of death, intimate and caring relationships are the fundamental mediators of successful human development. Those that are created in the earliest years . . . constitute a basic structure within which all meaningful development unfolds.” The critical role of early relationships has been effectively established by Egeland, Sroufe, and their colleagues in their work with children of low-income mothers. Based in Bowlby’s (1988) attachment theory, these scholars argue that individuals’ adaptation is always a product of both their developmental histories and current life circumstances—never of just one of these. Early experience places people on probabilistic trajectories of relatively good or poor adaptation, shaping the lens through which subsequent relationships are viewed and the capacity to utilize support resources in the environment. Thus, if early attachments are insecure in nature, at-risk children tend to anticipate negative reactions from others and can eventually elicit these; these experiences of rejection further increase feelings of insecurity (Allen, Hauser, & Borman-Spurrell, 1996; Sroufe, 2002; Weinfield, Sroufe, & Egeland, 2000). Conversely, at-risk children with at least one good relationship are able to take more from nurturant others subsequently encountered in development (Conger, Cui, Bryant, & Elder, 2000; Shonkoff & Phillips, 2000; Sroufe, 2002; Yates et al., 2003).

Among young children, the benefits of secure attachment have been demonstrated in diverse research paradigms. Research by Gunnar and her colleagues has shown that strong, secure attachments to caregivers can buffer or prevent elevations of stress hormones in situations that usually elicit distress in infants. In contrast, children with insecure attachments to caregivers tend to react to potentially threatening situations with increased levels of the stress hormone, cortisol (see Gunnar, 2000). In a literature review on the ontogeny of the two arms of the stress system, the limbic-hypothalamic-pituitary-adrenocortical and brain stem norepinephrine/sympathetic-adrenomedullary systems, the authors concluded that individual differences in the reactivity and regulation of both these systems are related not only to temperamental characteristics but also to quality of caregiving (Gunnar & Davis, 2003).

Even among older children and adolescents, competent parenting plays a critical role in promoting competent child outcomes over and above the effects of contextual factors such as parents’ socioeconomic status (Werner & Smith, 1982, 1992). To illustrate, among 6- to 12-year-old African

American youth in poverty, supportive mother-child relationships were linked both concurrently and prospectively with children’s depressive mood and disruptive behavior (Klein & Forehand, 2000). In two cohorts of low-income, urban youth (of 7- to 9-year-olds and 9- to 12-year-olds) in the Rochester Child Resilience Project, resilient status was significantly more likely among those dyads where parents were emotionally responsive and had relatively good mental health and high psychosocial resources (Wyman, Cowen, Work, & Parker, 1991; Wyman et al., 1999).

Even when risk factors stem from within the family, as when one parent has a mental illness, a strong relationship with the other parent can be substantially protective. Among children of alcoholics, Berlin and Davis (1989) found that the mother’s support and nurturance were important in leading to nonalcoholic outcomes of offspring during adulthood. Similarly, McCord (1988) demonstrated the critical role of the nonalcoholic spouse as someone who could help the child to differentiate from the father’s alcoholism, and Beardslee (2002) underscored the importance of strong, supportive relationships with at least one parent in families affected by parental depression.

The protective potential of strong relationships has been demonstrated not only for mothers but also for fathers and father figures, as seen in several studies of low-income, African American families. Fathers who were nurturant, satisfied with parenting, and employed had children with fewer behavior problems (Black, Dubowitz, & Starr, 1999). In addition, warm, close relationships with fathers (even those not living in the same house) benefited children in terms of lower levels of behavioral problems and higher self-esteem and less depression (Zimmerman, Salem, & Maton, 1995). In her review of the literature on low-income, unmarried, and minority fathers, Coley (2001) noted the widespread but insufficiently studied phenomenon of “social fathering,” wherein men other than biological fathers fulfill the father-figure role. Among low-income, African American preschoolers, between a third to half had a father figure involved with them; among adolescents, 24% nominated a nonbiological father figure when asked to name a man who was “most like a father” to them (Coley, 2001).

Whereas several studies have shown that children benefit from close involvement with fathers, some also have indicated that father involvement can sometimes be related to negative outcomes (see Coley, 2001; Leadbeater, Way, & Raden, 1996). Such findings may reflect elevated conflict between highly involved fathers and mothers, deriving, for example, from disagreements about disciplinary practices for their young children (Shaw, Owens, Vondra, Keenan, &

Winslow, 1996). Additionally, some young children of highly involved fathers in poverty may be exposed to high levels of paternal problem behaviors, such as antisocial behaviors and substance abuse (Jaffee, Moffitt, Caspi, & Taylor, 2003; Leadbeater et al., 1996). As Coley has noted, we need more research to disentangle these findings, teasing apart, for example, the effects of different types of father involvement such as emotional and financial involvement, as well as the amount of time spent with the child.

Apart from primary caregivers, siblings can help modify the effects of high-risk circumstances. In their research with sibling pairs in rural African American families, Brody (2004) and his colleagues demonstrated that the older siblings' competent behaviors at school were linked with increases in younger siblings' competence over time, through the intervening variable of younger siblings' self-regulation. Conversely, siblings also can exacerbate vulnerability in at-risk families. In families with one child already at high risk for deviant behaviors, Bullock and Dishion (2002) found that the deviance of siblings was promoted by collusion in the presence of adult caregivers. Furthermore, sibling collusion was found to uniquely predict adolescent problem behavior over and above associations with deviant peer groups.

A potentially critical source of support to at-risk children lies in extended kin, with the beneficial effects occurring directly as well as indirectly via their parents' adjustment (Elder & Conger, 2000; McLoyd, 1997). Grandparents often provide substantial emotional and material support directly to their grandchildren; in fact, they may sometimes be more willing to offer support to grandchildren than to their own children, such as when the latter have problems of substance abuse (Apfel & Seitz, 1997). Indirect effects involving parents are evident in findings that kin support can bolster authoritative parenting behaviors, feelings of well-being, and involvement in children's schools, benefits that are reflected, in turn, in positive child adaptation (R. D. Taylor, 1996; R. D. Taylor, Casten, & Flickinger, 1993).

Correcting Lack of Parent Nurturance

Whereas early relationships are critical in shaping the lens through which people view their subsequent interactions, a faulty lens can be corrected to some degree. In general, developmental psychopathologists maintain that there is continuity and coherence in development so that positive adaptation in early years determines, in probabilistic rather than determinative fashion, the likely success at later stages (Carlson, Sroufe, & Egeland, 2004; Sroufe, Carlson, Levy, & Egeland, 1999; Yates et al.,

2003). At the same time, scholars acknowledge that lawful discontinuities often do occur, and in the context of attachment status these frequently derive from changes in the caregiving environment (Egeland & Sroufe, 1981; Sroufe et al., 1999; Thompson, 2000; Waters, Weinfield, & Hamilton, 2000).

Such lawful discontinuities are illustrated by findings that children show a shift from secure to insecure patterns if the availability of the primary caregiver becomes attenuated due to circumstances such as maternal depression or chronic illness or life events such as parental divorce (Waters, Merrick, Treboux, Crowell, & Albersheim, 2000; Waters, Weinfield, et al., 2000). In longitudinal research spanning infancy through adulthood, individuals' insecure attachment at the age of 18 years was not related to insecure status at 1 year, but it was significantly related to experiences of parental divorce in the intervening years (Lewis, Feiring, & Rosenthal, 2000).

Intervention studies also provide consistent evidence with regard to the possibility of shifting attachment status, as seen in work by Heinicke and his colleagues (Heinicke, Rineman, Ponce, & Guthrie, 2001). Among young children of low-income mothers, these investigators offered a relationship-based intervention aimed at fostering mother's encouragement of infants' autonomy and self-regulation, as well as development of a secure attachment. Children of intervention mothers were in fact more securely attached, more autonomous, and more task-oriented 2 years later. Similar evidence is seen in Cicchetti and colleagues' (Cicchetti, Toth, & Rogosh, 1999) intervention for young children of depressed mothers.

Parallel lawful discontinuities have been documented in terms of shifts from insecure to secure attachment status as a function of ameliorative relationship experiences. Dozier (Dozier, Albus, Fisher, & Sepulveda, 2002; Dozier, Stovall, Albus, & Bates, 2001) has shown that among children entering foster care, all of whom experienced significant disruptions in relationships with caregivers during the 1st year and a half, insecure early attachments were remediated to some degree by intervention services and foster caregivers' positive qualities of nurturance, responsiveness, and their own attachment state of mind. Similarly, among low-income children with insecure and avoidant patterns of early attachment, several came to show secure attachments by adulthood, manifesting good parenting behaviors themselves and close relationships with romantic partners (Roisman, Padron, Sroufe, & Egeland, 2002). Again, the shift in attachment status was seen as deriving from positive experiences with caregivers through the later childhood and adolescent years.

In other longitudinal research, the corrective power of good relationships is seen in Rutter's (1987) classic study of women who had been institutionalized as young children. When these women were grown, those who had good marital relationships—characterized by harmony and a warm, supportive spouse—showed good parenting behavior much more frequently than did ex-care women who lacked such marital support. More recently, among delinquent adolescent boys followed through the age of 70 years, Laub and Sampson (2003) found that changes in rates of crime over time were generally unrelated to childhood risk factors but were systematically linked with adult transitions to marriage, unemployment, and military service. The effects for marriage were the strongest, accounting for as much as a 40% reduction in the rate of criminal offending. The authors viewed the effects as involving nurturance as well as informal social control: "Men who desisted from crime were embedded in structured routines, socially bonded to wives, children, and significant others, drew on resources and social support from their relationships, and were virtually and directly supervised and monitored" (p. 279; see also Conger, Rueter, & Elder, 1999; Vaillant & Davis, 2000).

Research with adults also has yielded some biological evidence on the benefits of good relationships. In one study mapping quality of adults' relationships and their physical health, the researchers derived cumulative relationship pathways encompassing prior relationships with parents and current ones with spouses. Individuals were defined as being on the positive relationship pathway if they had had at least one parent who was affectionate and caring and, as adults, had at least one of two forms of intimacy with their spouse: sexual or intellectual/recreational. Those on the negative relationship trajectory had poor bonds with both parents and/or had a marriage low on both intimacy dimensions. The investigators then examined whether cumulative relationship profiles were related to levels of allostatic load (a measure of the cumulative wear and tear on multiple physiological systems, including metabolic, cardiovascular, HPA axis, and sympathetic nervous system). As predicted, people on the positive relationship pathways were significantly less likely than those on negative pathways to show high allostatic load. Furthermore, positive relationships were found to serve as buffers against persistent economic adversities: In the presence of economic risks, only 22% of those with positive relationship pathways showed high allostatic load, compared with 69% of those with negative relationship pathways. Although the authors conceded the relatively preliminary nature of their findings, the findings were seen as illustrating

a type of biopsychosocial pathway of resilience warranting further empirical attention (Ryff & Singer, 2002; see also Evans, 2003; Reis & Collins, 2004).

The reversibility of early insecure attachments depends on the duration and severity of early deprivation, as seen in research on children adopted into United Kingdom families following early severe deprivation in Romanian orphanages, and a comparison sample of nondeprived within-UK adoptees. In the sample of deprived adoptees, dose-response associations were found between duration of deprivation (as indexed by age at which children were adopted) and atypical patterns of attachment to adoptive parents (O'Connor & Rutter, 2000). Research by Gunnar and colleagues (Gunnar, Morison, Chisholm, & Schuder, 2001) showed similar dose-response effects with levels of the stress hormone cortisol as the outcome of interest. Six and a half years after adoption, children reared in Romanian orphanages for more than 8 months in their first years of life had higher cortisol levels over the daytime hours than did those adopted before 4 months of age. For the former group, furthermore, the longer the period of institutionalization beyond 8 months, the higher their cortisol levels.

Over a longer developmental period, dose-response associations are evident in findings on ramifications of family climate during early childhood, middle childhood, and early adolescence for intergenerational relationships between participants at age 26 years and their parents (Belsky, Jaffee, Hsieh, & Silva, 2001). Results showed that unsupportive child rearing during one of the three developmental periods could be offset if family relations in the other two periods were relatively supportive. Such amelioration was not found if two of the three periods reflected disruptions.

It is unclear, however, whether the quality of these "corrected" relationships is entirely comparable to that experienced by individuals who did not face early risks. In another study of the children in Romanian orphanages, Rutter and O'Connor (2004) showed that at the age of 6 years, most of these children showed social and cognitive functioning in the normal range after being adopted into British families. At the same time, a substantial minority manifested major persistent deficits. The pattern of findings was interpreted as suggesting some form of early biological programming or neural damage stemming from institutional deprivation and also, given the heterogeneity in outcome, that the effects are not deterministic (Rutter & O'Connor, 2004). Other research has shown that among ex-institutionalized children, a nontrivial group do fail to develop secure attachments with adoptive or foster parents and have difficulty forming intimate relationships later in

development (Hodges & Tizard, 1989; O'Connor et al., 1999). Treboux, Crowell, and Waters (2004) found that when adults had insecure attachment representations based on early relationships but secure attachments in current relationships with partners, they were more reactive to stress than were those who had secure attachments in both early and current relationships. Finally, in Werner's (Werner & Smith, 1992) 30-year follow-up, children who had initially seemed resilient despite several life adversities came to show some difficulties in achieving intimacy in their adult relationships.

Protective Parenting: Discipline and Monitoring

In addition to dimensions of attachment, another broad parenting construct critical for resilient adaptation falls in the broad domain of discipline: limit setting and monitoring. Limit setting refers to the use of appropriate rules and expectations in shaping socially desirable behavior in the child. The degree to which parents clearly define limits and consistently enforce rules is critical in shaping the child's future compliance (Cavell, 2000; Schneider, Cavell, & Hughes, 2003). Conversely, inappropriately harsh discipline exacerbates vulnerability to maladaptive behaviors. As Patterson (1983) theorized, when parents respond to young children's annoying behaviors in ways that are coercive and based on power assertion, children tend to escalate their own aversive behaviors in attempts to control the parents. As the child's aversive behaviors increase in intensity and frequency, parents sometimes acquiesce, thereby reinforcing the maladaptive behaviors. Conversely, if parents resort again to power-assertive and harsh techniques, they come to serve as role models for hostile behavior patterns.

Patterson's (1983) coercion theory is at the core of Shaw and colleagues' research on the importance of appropriate limit setting for young children (for an overview, see Shaw, Bell, & Gilliom, *in press*). These researchers followed two cohorts of low-income mothers and their children, first assessed when the children were about 1 year of age. The authors postulated that when mother was unresponsive to infant's continued bids for attention, this tended to lead to later coercive exchanges between mother and child by age 2, which in turn would be linked with elevated risk for externalizing behavior problems by age 3. These postulates were supported in analyses based on both cohorts of mother-child dyads (Shaw et al., *in press*).

In another set of studies, the focus was not on maternal unresponsiveness but hostility. Noting toddlers' tendencies to evoke frustration from caregivers (e.g., because of their increase in mobility and assertion of independence), the re-

searchers noted that a critical developmental task for mothers is the capacity to maintain a nonhostile, relatively positive approach while shaping the child's behaviors. During a laboratory clean-up task, when mothers of 2-year-olds were observed to show rejecting behaviors, the children displayed a heightened risk for conduct problems at 3.5 years (Shaw et al., *in press*). When such rejecting, overcontrolling behaviors reflected a general parenting approach, children showed escalated risk for conduct problems not only at home but also at school, with such effects documented during the preteen years and adolescence (Shaw et al., *in press*; see also Dishion & Kavanagh, 2003).

Related to limit setting and also important for resilient adaptation is the construct of parental monitoring, which is defined as a "set of correlated parenting behaviors involving attention to and tracking of the child's whereabouts, activities, and adaptations" (Dishion & McMahon, 1998, p. 61). The salutary effects of consistent parental monitoring across various high-risk circumstances have been demonstrated from the elementary school years onward (Buckner et al., 2003). In a group of inner-city 8- to 10-year-olds, Chilcoat and Anthony (1996) found that those with high parental monitoring manifested a 2-year delay in the subsequent onset of drug use when compared with those in a low parental monitoring group. Other studies have shown links with positive indices of adjustment such as scholastic achievement and self-esteem (see Dishion & Kavanagh, 2003; Romer, 2003).

The benefits of consistent parental monitoring are particularly pronounced among preadolescents and adolescents, who have increasing independence from parents and thus growing exposure to a host of risks in the peer and community environments. Haapasalo and Tremblay (1994) reported that high parental supervision was a distinctive characteristic among low SES boys who consistently displayed low levels of physical aggression between the ages 6 and 12 years. More so than their aggressive counterparts, these nonfighters indicated that their parents were constantly aware of where and with whom they spent their free time through the period spanning the preadolescent years. Among low-income 8- to 17-year-olds, Buckner et al. (2003) found that of several variables external to the child, only parental monitoring significantly differentiated resilient from nonresilient youths, and a study of sixth graders with deviant peers showed that firm parental control inhibited the development of externalizing problems in later years (Galambos, Barker, & Almeida, 2003; see also Brody et al., 2002; Lloyd & Anthony, 2003). Studies have shown also that when their parents tend to know of their daily activities and associations, adolescents are less likely

to engage in delinquent behavior, drug use, risky sexual activity, and association with gangs (Dishion & Kavanagh, 2003; Romer, 2003).

Links between parent monitoring and adolescent adjustment are not always simple linear ones, but can depend on coexisting risks in the environment or even be curvilinear. To illustrate, Mason, Cauce, Gonzales, and Hiraga (1996) showed that in terms of ramifications for children's problem behaviors, optimal levels of control exerted by African American parents varied according to negative influences in the community. When adolescents reported relatively high problem behaviors in their peer groups, for example, optimal levels of parental control tended to be higher than when children's peer problem behaviors were low.

In terms of underlying processes, ethnographers (Burton et al., 1995; Jarrett, 1999) have delineated several expeditious limit-setting strategies used by inner-city families. These include the avoidance of dangerous areas, temporal use of the neighborhood (e.g., avoiding being outside in the evening hours), and restriction of children's relationships with deviant peers. Other posited mechanisms include those resting on psychological processes: Continuity and structure in the adolescent's environment can promote the development of effective coping skills, and when parents impart a sense of interest and concern for the adolescent's well-being, this tends to enhance children's self-esteem (Buckner et al., 2003; Luthar, 1999).

Related to monitoring—in some ways, the converse of it—is autonomy granting, also important for resilient adaptation. Observational research involving mother-infant interactions suggests that maternal support of exploration and autonomy (versus maternal restriction and control) is associated with the child's mastery motivation, persistence at tasks, competence, self-regulation, and positive affect through subsequent years (see Bornstein, Davidson, Keyes, & Moore, 2003; Shonkoff & Phillips, 2000). Among older children, perceptions of their own autonomy are linked with various indices of adaptive development such as academic engagement and prosocial behavior (Bornstein et al., 2003).

Autonomy has high significance during the teen years as well. A major developmental task of adolescence is to negotiate the struggle between the development of autonomy on the one hand, and the maintenance of close bonds with parents on the other. Among youth at high risk by virtue of psychiatric hospitalization, observed autonomy and relatedness displayed by both parents and adolescents were related to high levels of adolescents' self-esteem as well as their ego development (Allen, Hauser, Bell, & O'Connor, 1994). In a subsequent study of this cohort 11 years later,

maternal behaviors promoting adolescent autonomy and relatedness were also associated with coherence/security of attachment during adulthood (Marsh, McFarland, Allen, McElhaney, & Land, 2003).

As was seen in relation to parental monitoring, the optimal level of autonomy granted to adolescents can vary as a function of sociodemographic disadvantage. This is seen in McElhaney and Allen's (2001) research with adolescents living in urban poverty. Among these youth, maternal behaviors undermining of children's autonomy (i.e., interrupting them to shut down discussions) was positively linked with mother-adolescent relationship quality, whereas among low-risk comparison youth, links were inverse in nature. The authors suggest that behaviors potentially seen as overprotective might be seen as expressions of care and concern among youth in high-risk contexts, although they tend to be seen as inappropriately inhibiting and even guilt producing by adolescents in low-risk settings. Finally, the possibility of curvilinear effects is seen in research on adolescents at risk because of problems at school (such as grade retention or school suspension). When mothers were low in autonomy granting, adolescents with insecure preoccupations were found to be vulnerable to high internalizing problems. Conversely, if mothers were excessively high on autonomy granting, vulnerability to externalizing behaviors was pronounced (Marsh et al., 2003).

Coexisting Warmth and Appropriate Control

Whereas high levels of warmth and appropriate control each have protective functions, the benefits of each depend to some degree on levels of the other: High warmth with lax discipline can be linked with poor adjustment, as can strict discipline without affection. The authoritative parenting style, characterized by the appropriate balance of parental warmth and control (Baumrind, 1989), is generally optimal; authoritative parents are defined as those who "are warm, supportive, communicative, and responsive to their children's needs, and who exert firm, consistent, and reasonable control and close supervision" (Hetherington & Elmore, 2003, p. 196).

Among low-income mothers, efforts to facilitate warm and responsive interactions with infants or toddlers enhanced the quality of future discipline techniques, in turn serving as a powerful force against externalizing disorders in childhood and adolescence (Shaw et al., 1996). In a related vein, among rural African American families, the development of adaptive self-regulatory behavior was significantly enhanced by mothers who provided support along with structure and clear behavioral expectations,

even among children with difficult temperaments. Moreover, positive parenting promoted greater self-regulation than both individual child and community protective factors (Murry & Brody, 1999). Authoritative parenting also has repeatedly been found to promote resilience in children facing disruptions in family life due to divorce (Hetherington & Elmore, 2003).

Timothy Cavell (2000) has emphasized the importance of an appropriate balance of warmth and discipline in the notion of parental *containment*, which is “any behavior that fosters in children a sense of restraint while not threatening their relationship security” (p. 131). Recent studies have pointed to the protective potential of this construct. Building on Cavell’s arguments on the significance of children’s beliefs about the likelihood of being disciplined, Schneider et al. (2003) defined perceived containment as the child’s beliefs concerning the parent’s capacity to enforce firm limits and the likelihood that the parent will prevail in conflict. They found that children with a particularly strong sense of containment had a mother who applied effective discipline in the context of an emotionally positive relationship. Furthermore, high perceived containment was protective against externalizing behaviors as rated by parents and teachers (Schneider et al., 2003).

Intervention studies with at-risk youth further buttress the conclusions from basic research on the importance of firm, consistent discipline in the context of supportive parent-child relationships (see Biglan & Taylor, 2000; Webster-Stratton & Taylor, 2001). In a review of the literature, Kumpfer and Alvarado (2003, p. 457) note, “Effective parenting is the most powerful way to reduce adolescent problem behaviors”; they describe three approaches that have generally been successful. The first includes behavior training approaches that are highly structured and involve working only with parents; the second entails an integration of parent behavior training and children’s social skills training, both administered in group format; and the third involves family therapy programs that are administered with individual families.

Underlying Processes and Other Potentially Important Dimensions: Future Research Needs

Whereas good relationships are clearly critical for resilience, there remain several questions about the active ingredients therein: What are the core processes that might explain this effect? The most obvious mechanism is that discussed earlier: that early attachments shape the lens through which later interactions are viewed. However, there are various other parenting constructs that probably

coexist with generally good parenting and warrant further study, one of which is children’s trust that the parent will shield or protect them against danger (an interesting parallel to perceived containment, children’s beliefs that the parents will be able to discipline effectively). In their research with children who experienced foster care, Dozier and colleagues (Dozier, Lindhiem, & Ackerman, in press) found that possibly even more than security of early attachment, foster parents’ investment in their children was particularly powerful. When foster parents were highly invested in their children (as assessed through an interview), the children fared better not only in terms of neuroendocrine regulation but also, several years later, in self- and other representations. Among children who have experienced the considerable disruptions of early foster placement, therefore, the authors speculate that an important factor might be the child’s confidence that the caregiver will stand between him or her and danger, rather than whether the caregiver will comfort the child when distressed. They suggest that this component of the attachment system is not assessed in the standard assessment of attachment among human young (the Strange Situation), but is a key component of attachment assessed among non-human primates.

Also warranting more attention is the role of simple family routines. In their study of rural, single-parent African American families, Brody, Flor, and Gibson (1999) defined effective parenting not only in terms of mother-child relationship quality and school involvement, but also family routines, as measured by variables such as “Family has a ‘quiet time’ each evening when everyone talks or plays quietly,” and “Working parents come home from work at the same time every day.” Among youth at the two extremes of family socioeconomic status, Luthar and Latendresse (2005b) showed that even after considering indices such as emotional closeness and parental supervision, a simple indicator of time spent together—eating dinner with at least one parent most evenings—was significantly related to several child outcomes (see also National Center on Addiction and Substance Abuse, 2002). In terms of underlying mechanisms, the findings could reflect either of two patterns: that parents are typically not at home late in the evenings, or that they are present but do not eat with their children. Both options could lead the average 12-year-old to feel psychologically adrift and to do things that parents would disallow had they been at home, including experimentation with substances and the blatant neglect of homework (Luthar & Latendresse, 2005b).

Beyond these specific parenting constructs, Rutter (1987) noted various possible mechanisms to explain why,

in the context of family adversity, a good relationship with one parent can confer protection processes. There could, for example, be less overall disruption when one relationship in the family is harmonious; the “close” parent can ensure that the child is away from the home at times when things became particularly difficult; this parent can help the child understand the origins and nature of the family’s problems; or the security of the good relationship can increase the child’s self-esteem, and this in turn confers protection. Despite exhortations almost 2 decades ago that underlying processes need to be understood (Rutter, 1987), there has been relatively little headway in disentangling the relative importance of such processes in conferring protection not only during childhood but also beyond, extending into the adult years. Much more needs to be done on this front.

Parenting as a Dependent Variable

Another set of issues critically needing more empirical attention pertains to the ways children affect parents’ mental health. By far most of child development research has been focused on the ways parents’ behaviors influence children, but some have shown that children’s behaviors might affect parents’ behaviors and even their psychological functioning (e.g., Garcia Coll, Surrey, & Weingarten, 1998; Luthar, Doyle, Suchman, & Mayes, 2001). A study of more than 300 families showed that young children’s difficult temperaments were associated with their mother’s sense of parent competence and depressed affect, which in turn were related to their work outcomes—work role quality and rewards from combining work and family (Hyde, Else-Quest, Goldsmith, & Biesanz, 2004). In their study of sibling pairs in rural, African American families, Brody (2004) and his colleagues found that older siblings’ competence levels significantly contributed to changes in mother’s psychological well-being over time and that children’s competence forecast mother’s supportive and involved parenting a year later.

More broadly, we need more research focusing squarely on the parents’ functioning, understanding what it is that allows some individuals to be effective parents in spite of serious stressors affecting their family. Juxtaposed with findings on the protective power of good parenting, unfortunately, is the inescapable fact that this very factor is substantially imperiled under the risk circumstances commonly considered in resilience research (Luthar & Zelazo, 2003). Adverse effects on parenting have been documented for risks ranging from chronic poverty (Owens & Shaw, 2003) to parental mental illness (Seifer, 2003) and family disruptions such as divorce (Hetherington & Elmore,

2003); child maltreatment by definition implies a disturbed parent-child relationship. Despite knowledge of these threats to parenting, it is curious that among at-risk families, good parenting is relatively rarely examined as an outcome domain, but far more often examined in terms of its associations with children’s developmental outcomes.

Little is understood also about pathways or mechanisms to positive parenting; although families are commonly viewed as engines of change in early interventions, the mechanisms by which parenting improves remains largely opaque. Reviewing the early childhood intervention literature, Brooks-Gunn, Berlin, and Fuligni (2000) note that several programs have led to improvements in parenting dimensions, but most programs do not encompass explicit theories on pathways through which improvements actually occur. It is conceivable, for example, that change essentially occurs because mothers receive increased emotional support (which in turn can lead to reduced stress and improved mental health), or because mothers have learned new coping skills and parenting behaviors (which leads them to feel more efficacious and empowered), or some combination of these possibilities (e.g., Bishop & Leadbeater, 1999). Disentangling the relative salience of such mechanisms should be a priority in future research on resilience.

Processes Unique to Ethnic Minority Subgroups

Families’ ethnic minority status often represents a salient vulnerability factor in today’s world, yet there continues to be a troubling dearth of studies that explicitly address socializing influences and challenges specifically among minority families. There are clearly some universals in children’s social-emotional development—the previously highlighted power of supportive caregiving is but one—but at the same time, one-model-fits-all perspectives are of limited value (García Coll et al., 1996; Luthar, 1999). Ethnic minority parents contend with several unique challenges in socializing their children.

In a seminal article on these issues, García Coll and colleagues (1996) provide a useful framework that can guide researchers in studying critical socializing influences in ethnic minority groups. Anchored in social stratification theory, the integrative model posits that there are eight major sets of constructs that affect the development of minority children: (1) social position variables (e.g., race or social class, gender); (2) racism and discrimination; (3) segregation; (4) promoting/inhibiting environments (school, neighborhoods, and health care); (5) adaptive culture (traditions and legacies); (6) child characteristics such as age and temperament; (7) family values and beliefs; and

(8) developmental competencies in the cognitive and social-emotional domains.

Of the various challenges they confront, perhaps the single greatest is poverty: Families of color are highly over-represented in poverty groups. In 2002, 58% of all African American children and 62% of Hispanic children live below the national poverty level, as compared with 25% of White children (http://www.nccp.org/pub_cpf04.html). Furthermore, their low-income status accounts for much of the psychosocial maladjustment that has been documented. Studies show that once income is taken into account, African American youth can fare not just as well as but even better than their Caucasian peers in terms of mental health indices as well as competent behaviors (see Luthar, 1999). Similarly, Hashima and Amato (1994) showed that with income controlled, ethnic minority parents were no different from their White counterparts in terms of the frequency of harsh or punitive parenting behaviors.

Aside from poverty, racism and discrimination are powerful challenges in the daily lives of minority families, so much so that they are now considered to be essential ingredients in research on minority children's development (Bigler, Averhart, & Liben, 2003; Garcia Coll, Meyer, & Brillion, 1995; D. Hughes, 2003; Oyserman, Bybee, & Terry, 2003; Spencer, Fegley, & Harpalani, 2003; Spencer, Noll, Stoltzfus, & Harpalani, 2001). In a literature review, Szalacha and colleagues (2003) cite nationwide survey findings that 44.4% of non-Hispanic Whites reported that they had never experienced day-to-day discrimination, in contrast to only 8.8% of non-Hispanic Blacks; parallel frequencies for often experiencing discrimination were 3.4% and 24.8%, respectively. In a sample of African American adults, 98% reported personally having experienced a racist event in the prior year—such as being treated badly by various people or having one's intentions misunderstood because of being Black—and 100% had experienced such in their lifetime (Landrine & Klonoff, 1996). Research with Hispanics similarly showed that 94% reported that they experienced some racist event in the past year; over 70% reported being treated unfairly by people in service jobs; and 50% indicated that their lives would be different if they had not been treated in a racist manner during the past year (Szalacha et al., 2003).

Racial and ethnic discrimination experiences are de-meaning and degrading, inducing stress as well as feelings of frustration, depression, and anxiety (Brown et al., 2000; Williams, Yu, Jackson, & Anderson, 1997). In survey research of teens from various ethnic backgrounds, all of the minority youth in the sample reported distress associated with perceived racial prejudice in educational contexts,

and their self-esteem scores were negatively correlated with that distress (Fisher, Wallace, & Fenton, 2000). Similarly, Szalacha and colleagues (2003) report that among Puerto Rican children, perceived discrimination was related to high levels of depression, stress, and conduct problems, as well as low self-esteem. Furthermore, even worrying about discrimination (reported by nearly half the youth in this sample) was a risk factor for lower self-esteem. These findings resonate with Franklin's (1999) arguments that ethnic minority individuals' inner vigilance for racial slights can create a state of constant watchfulness, leading to chronic tension and feelings of stress.

Studies of adults also have shown that institutional racism has powerful effects on minority mental health (see Rollock & Gordon, 2000). In a nationwide study, Kessler, Mickelson, and Williams (1999) found that reports of day-to-day and lifetime discrimination were related to general psychological distress and depression. Landrine and Klonoff (1996) found that the individuals reporting racist events had relatively high depression and anxiety, as well as somatization and obsessive-compulsive symptoms. In a review of the public health literature, Krieger (1999) found recurrent links between perceived discrimination and levels of stress, psychological distress, and depression.

In terms of underlying mechanisms, vulnerability is likely to be conferred by two processes: (1) the internalization of negative feedback and the stress attributable to repeated exposure to discrimination, and (2) the associated anxiety that one will be a victim of discrimination (see Szalacha et al., 2003). Furthermore, bidirectional links are possible, wherein psychological factors—such as high depression and anxiety, or low intergroup competence—can predispose people to perceive discrimination (e.g., Phinney, Madden, & Santos, 1998).

The likelihood of perceiving discrimination can be suppressed somewhat by factors such as ethnic pride and biculturalism, as well as attributional ambiguity. Racial socialization, ethnic pride, competence in relating to others of different racial/ethnic groups, and biculturalism have all been documented as mitigating the negative effects of discrimination (García Coll et al., 1995; Phinney et al., 1998; Spencer et al., 2003; Szalacha et al., 2003). Experiments have shown that if people can attribute negativity to another's prejudice, this can render discrimination irrelevant to their self-views (Ruggiero & Taylor, 1997). But it should be emphasized that the likelihood of such attributions obviously diminishes as experiences of discrimination are continually encountered over time (Szalacha et al., 2003).

Other environmental forces involved in heightening risks for minority families are those at the neighborhood level. If they are poor, minority group children are more likely than Caucasians to live in neighborhoods where institutional supports are meager (Duncan, Brooks-Gunn, & Klebanov, 1994). Among African American children more than their Caucasian counterparts, male joblessness in the neighborhood is linked with increased risk for externalizing behavior problems (Chase-Lansdale & Gordon, 1996). Drawing on Wilson's (1991) writings on social isolation, authors of this study reasoned that in inner-city neighborhoods with high male joblessness—areas in which African Americans are disproportionately represented—the dearth of role models of disciplined behaviors, which accompany regular adult employment, can significantly exacerbate behavior problems among African American youth.

Similar suggestions involving social structures have been offered in explaining findings that academic failure can increase risk for subsequent delinquency among Black youth more than among Whites (e.g., Lynam, Moffitt, & Stouthamer-Loeber, 1993). Many of these youngsters are unconvinced that success at school will lead to success in later life due to their ongoing experiences with racism and marginalization and perceptions of job ceilings that deny them access to prestigious jobs (see Arroyo & Zigler, 1995; Ogbu, 1991; Spencer et al., 2001). Even among those minority students who do invest in school, exposure to negative stereotypes about their scholastic abilities tends to trigger high anxiety, which in turn can substantially jeopardize the level of academic success they are able to achieve (Steele, 1997). When African American boys become frustrated with school as a result of academic failure, they often remove themselves from its social control and thus become vulnerable to alternative social influences—often those of delinquents in the unstable, socially isolated neighborhoods in which Blacks are overrepresented (Wilson, 2003).

Immigrant families are among the most vulnerable at many levels. For example, Hispanic parents experience several unique stressors related to migration, acculturation, difficulties with language, and social isolation (Sanders-Phillips, Moisan, Wadlington, Morgan, & English, 1995). As Garcia Coll and Vasquez García (1995) noted, new Hispanic immigrants to the United States must acculturate not only to an alien culture and language but also, frequently, to urban poverty at the same time. In addition, aspects of cultural values can lead to problems. For example, Latino children can find it difficult to negotiate the value placed on individuation and separation in the mainstream White American world with the emphasis on obedience to and respect for elders of Latino culture (Sanders-Phillips et al.,

1995). Among Latino youth, the consistency of values between youth and their parents was the key predictor of low levels of risky sexual behavior (Liebowitz, Castellano, & Cuellar, 1999).

These very differences can also, however, confer protection; the value of family connectedness, for example, brings loyalty and support from kin. Research by Fuligni and his colleagues (Fuligni, Tseng, & Lam, 1999) showed that Asian and Latin American adolescents possessed stronger values about their duty to respect, support, and help their family than their peers of European backgrounds. Furthermore, emphasis on family obligations tended to be associated with more positive relationships with family and peers as well as higher academic motivation among mid- to late adolescents. In other research, educational resilience among Latino youth was strongly associated with supportive relationships in families (Arelano & Padilla, 1996). As Szalacha and colleagues (2003) noted, “la familia,” a core cultural characteristic of Latino cultures, is appropriately beginning to be included in studies of resilience among Latino youth (Falicov, 1996; McNeill et al., 2001). Finally, several studies involving African American families have shown that extended kin support helps promote positive outcomes among both parents and children in poverty (Luthar, 1999). The benefits of social supports for parents are evident in increases in their greater well-being and positive parenting behaviors, benefits that are reflected, in turn, across several domains of child adaptation, including behavioral conformity and school achievement (Burchinal, Follmer, & Bryant, 1996; R. D. Taylor, 1996; R. D. Taylor et al., 1993).

As with strong family values, acculturation to mainstream America can have both positive and negative effects. Among Hispanic individuals, for example, higher level of acculturation is linked with relatively high English fluency and low depression but, at the same time, with higher risk behaviors such as delinquency and pregnancy among youth and substance use among both adolescents and adults (see McQueen, Getz, & Bray, 2003; Rogler, Cortes, & Malgady, 1991). In terms of underlying mechanisms, alienation from the family seems to be implicated to some degree. With increasing acculturation can come some attenuation of familial obligations and influence of families as referents, along with greater family conflict and children's emotional separation from parents (Hill, Bush, & Roosa, 2003; McQueen et al., 2003).

Gene-Environment Interactions

An exciting set of new developments in the field of resilience is inquiry into the role of genetic contributions to

vulnerability and protective mechanisms in the family, as seen in the seminal research by Caspi and his colleagues. Two studies by this group identified specific genes implicated in protecting some maltreated children from developing psychopathology in adulthood. The first of these showed reduced likelihood of antisocial behavior in the presence of a genotype that confers high levels of the monoamine oxidase A enzyme (Caspi et al., 2002). In the second study, likelihood of developing depression was lower in the presence of a genotype conferring the efficient transport of serotonin (Caspi et al., 2003). Although the specific processes through which these gene markers exert their protective effects are unknown, it is possible that they operate by shaping aspects of children's social-cognitive reactions to life stressors, as in their propensity for attributional biases, for example, or capacities for emotion recognition (Kim-Cohen et al., 2004).

A subsequent study by Kim-Cohen and colleagues (2004) was the first to specifically examine both genetic and environmental processes in the resilience framework. The study involved an epidemiological cohort of 1,116 twin pairs from low SES families. Two aspects of resilience were examined—behavioral and cognitive—and results of quantitative genetic models showed that additive genetic effects accounted for approximately 70% of the variation in children's behavioral resilience and 40% of the variation in cognitive resilience.

Further analyses established protective effects of both maternal warmth and child's outgoing temperament, with each factor operating through both genetically and environmentally mediated effects. Specifically, 66% of the phenotypic correlation between maternal warmth and behavioral resilience was accounted for by genetic influences, and the remaining 34% by child-specific environmental influences. Similarly, 71% of the correlation between outgoing temperament and cognitive resilience was accounted for by genetic influences, 17% by environmental influences shared by the siblings, and 12% by environmental influences specific to the child. In addition, familywide environmental influences accounted for 22% of the population variation in cognitive resilience, and a significant contributor to this shared environmental factor was the degree of parents' provision of stimulating activities in the home.

The authors note several important inferences deriving from their findings. First, the additive genetic effects observed could each operate via either passive or active gene-environment correlations (Rutter, 2003; Rutter & Silberg, 2002). In the context of maternal warmth and behavioral resilience associations, for example, passive ge-

netic effects could result because parents who are warm and affectionate transmit genes to their children that promote good behavioral regulation; genes operate as a third variable, as it were, linking the other two. Active gene-environment correlations, by contrast, would derive if children had heritable characteristics that tended to elicit warmth from adults around them, and this in turn would help foster good behavioral regulation. Parallel explanations were provided for genetic contributions to links between outgoing temperament and cognitive resilience. In this case, passive correlations may derive because parents provided genes that affect both the child's disposition and his or her cognitive competence, whereas an active correlation could result if children's genetically inherited dispositions (e.g., sociability) led them to elicit more attention and learning experiences from adults. The disentangling of passive versus active components underlying such genetic effects constitutes an exciting new direction for future research.

A particularly critical conclusion drawn by these researchers, however, has to do with implications for interventions: *Heritability does not imply untreatability* (Plomin & Rutter, 1998; Rutter, 2002b). As Kim-Cohen et al. (2004, p. 14) note, their study entailed "a genetically sensitive design [demonstrating] that environmental effects can make a positive difference in the lives of poor children. . . . Even child temperament promoted resilience through environmental processes." Of vital importance is their conclusion that if families confronting the myriad stresses of poverty are helped to move toward warm, supportive parenting and providing stimulating learning materials, children can be helped to achieve greater behavioral and cognitive resilience.

At this stage, there are several important directions for future work involving gene-environment influences in resilience (Rutter, 2000, 2003). Twin and adoptee studies of at-risk children can be used to (1) examine the relative contributions of genetic versus environmental influences in the ways that different protective and vulnerability factors operate; (2) understand the mechanisms entailed in each of these (e.g., passive or active gene-environment mechanisms and critical influences underlying the environmental component); and (3) identify genetic markers that confer protection or vulnerability and describe processes underlying their effects. Also needed are sibling studies illuminating the relative contributions of shared versus non-shared extrafamilial environments on different outcomes. Finally, genetics research can contribute to new developments in the study of resilience through precise quantification of risk. As noted in the first section of this chapter,

risk is generally inferred based on statistical links between aspects of the environment (e.g., maltreatment or poverty) and children's maladjustment, but this measure of risk is imprecise at best. With knowledge that some children have genes conferring liability to particular disorders, examining factors in the lives of those who do not succumb could contribute vastly to our understanding of processes in resilience.

Communities: Effects of Violence

As with chronic maltreatment in the family, chronic exposure to violence in the community can have overwhelming deleterious effects, difficult for other positive forces to override and affecting multiple domains. Exposure to violence substantially exacerbates risks for internalizing problems such as anxiety, depression, and Posttraumatic Stress Disorder, as well as impaired academic performance due to disruptions in concentration and memory (for reviews, see Caue et al., 2003; Cooley-Quille, Boyd, Frantz, & Walsh, 2001; Garbarino, 1995; Margolin & Gordis, 2000; Osofsky, 1995). Also heightened is vulnerability to externalizing problems such as delinquent, antisocial behaviors, with prospective associations being significant even when controlling for previous levels of aggression (Gorman-Smith & Tolan, 1998; Miller, Wasserman, Neugebauer, Gorman-Smith, & Kam-boukos, 1999; Schwab-Stone et al., 1995).

There also has been increasing attention to effects on children's neurobiology, with suggestions that violence exposure, particularly repeated exposure early in development, can fundamentally alter neurological system development (e.g., Perry, 1997; Pynoos, Steinberg, Ornitz, & Goenjian, 1997; Pynoos, Steinberg, & Piacentini, 1999). During the early years, the central nervous system is believed to be particularly responsive to traumatic organizing and structuring experiences (Weiss & Wagner, 1998); brain development is seen as particularly sensitive to overarousal affecting the organization and development of specific brain areas (Perry, 1997). Thus, children exposed to trauma may experience abnormal neurological development due to overstimulation of certain brain structures, with the degree of impact depending somewhat on the developmental timing of the event(s). In addition, exposure to violence may also affect children's arousal and ability to react appropriately to stress. To illustrate, children exposed to trauma have been found to have increased overall arousal, increased startle response, sleep disturbance, and abnormalities in cardiovascular regulation (Curtis & Cicchetti, 2003; Perry, 1997).

Several aspects of violence can affect a youth's reaction to it, including proximity and relation to the violence (Gorman-Smith & Tolan, 2003). To illustrate, in a 14-month follow-up of children attending a school where a sniper shot 14 students on the playground, Nader, Pynoos, Fairbanks, and Frederick (1990) found that children on the playground had the most severe symptoms, followed by those in the school building, and then those not at school on that day. Another important factor is the child's relationship to the individuals involved: Children are most affected when the victim is someone close to them. P. Martinez and Richters (1993) found that only those incidents involving people known, as both victims and perpetrators, were significantly related to distress, and Jenkins and Bell (1994) reported that victimization of family members (witnessed or not) was as strongly related to psychological distress as was personal victimization.

In terms of family functioning, there is some modest evidence for the role of parents' functioning as mediators and moderators of community violence effects. When mother can appear calm and effective in the face of danger, children tend to do better than when the parent is either absent or is overwhelmed by the situation (Pynoos, 1993). Linares and colleagues (2001) showed that links between community violence exposure and children's behavior problems were mediated by maternal distress (Posttraumatic Stress Disorder as well as global distress), suggesting, again, that if maternal distress were kept low, this could attenuate the association between violence exposure and child maladjustment.

In the face of community circumstances where people's very survival is continually under threat, however, families are obviously constrained in how much they can confer psychological protection to children. This is evident from results of a collection of studies on violence exposure, all considering whether good family functioning might show "protective-stabilizing" influences: helping children to retain good adaptation even as exposure escalated. Considered together, the findings provided modest support at best for such effects (Hammack et al., 2004; Kliwer et al., 2004; Sullivan et al., 2004; see also Furstenburg, Cook, Eccles, Elder, & Sameroff, 1999; Miller et al., 1999). A common theme across all these studies was that positive family functioning (as represented, for example, by closeness to parents, time spent with them, level of perceived support) were beneficial at low levels of violence exposure. On the other hand, when violence exposure was high, the benefits of these variables tended to diminish, suggesting effects that were promotive in general (Sameroff et al., 2003) but not necessarily protective against the effects of community violence.

By contrast, *poor* family function does clearly exacerbate the risks of community violence: When children experience significant dysfunction in their proximal and their distal environments, their risk for psychopathology becomes substantial. In a study by Gorman-Smith and Tolan (1998), family structure (level of organization and support within the family) and cohesion (emotional closeness and support) were inversely linked to changes in both aggression and anxiety and depression for those exposed to community violence. Overall, the results corroborate the view that lack of a dependable, supportive refuge, or dearth of emotional connectedness to family, tends to exacerbate the risk for maladjustment for children exposed to high levels of community violence.

In view of accumulated evidence, the most obvious intervention direction is to reduce levels of violence, with efforts at both national policy and community levels addressing issues such as gun control and safety in schools (e.g., Bloomberg, Daley, Hahn, & King, 2004; Henrich, Schwab-Stone, Fanti, Jones, & Ruchkin, 2004; Ozer & Weinstein, 2004). As such policy-level initiatives are pursued, it is also critical to mobilize forces within communities and families, and Gorman-Smith and Tolan (2003) have provided some useful directions in this regard. The first involves efforts to shield children from violence through broad-based community efforts, involving coalitions of community groups and agencies (such as police, faith-based organizations). Examples include Operation Ceasefire in Boston, which sought to lower youth homicide through a direct attack on the illegal gun trade and creating a strong deterrent to gang violence (Braga, Kennedy, Waring, & Piehl, 2001), and the Child Development-Community Policing Program in New Haven, Connecticut (<http://info.med.yale.edu/chldstdy/CDCP/programs/overview.html>). The second level entails preventive interventions with families, such as their family-focused preventive SAFE Children intervention, aimed at promoting positive parenting practices within the ecological setting of urban poverty (Tolan, Gorman-Smith, & Henry, 2004). The third level involves therapeutic interventions for those exposed to the violence: services directed to the individual child and to caregivers or systems that can continue to provide support for the child (e.g., Pynoos, 1993).

Protective Processes in Communities: Early Intervention and Schools

Whereas the power of chronic exposure to violence in the community is rarely superseded by other protective processes, there certainly are exosystemic forces that can attenuate the ill effects of other types of adversities. Stud-

ies have pointed to the potential of the broader community to shape outcomes by affecting children themselves not only directly but also indirectly, via their parents.

In the early childhood years, the quality of child care can serve vital ameliorative functions, particularly as the home circumstances of children reflect increasing levels of risk. Reports by the National Institute of Child Health and Development (NICHD) Early Child Care Research Network (1997, 2002) suggest that for families living in or near poverty, mothers whose children are in high-quality child care tend to show more positive interactions with their infants. Furthermore, children of mothers who were very low on maternal sensitivity were more likely to be securely attached to them if the children were in higher-quality child care.

Results of several early childhood interventions also have shown protective effects accruing when highly disadvantaged children are provided with quality care (see Reynolds, 2000; Shonkoff & Meisels, 2000; Shonkoff & Phillips, 2000). A review by Yoshikawa (1994) showed that early intervention programs with long-term effects on chronic delinquency had not only early childhood components but also comprehensive family support. While the early education component attenuated child risks, family support reduced family risks and was deemed a necessary component for inhibiting at-risk children's later delinquency levels.

Of course, obtaining high-quality care is generally the most difficult for the poorest and most needy families. Among the major features defining quality of care, primary are the characteristics of the child care providers (e.g., their education and training), the child-to-adult ratios (e.g., with three or fewer infants per caregiver being advisable; see Shonkoff & Phillips, 2000), and stability of child care providers. Not surprisingly, these aspects of quality are often in jeopardy given the poor working conditions of most child care workers: The average hourly wage of child care workers in the United States is \$8.57 (the hourly wage of school bus drivers is \$11.33 and of animal trainers, \$12.48); turnover rates are among the highest of any profession that is tracked by the U.S. Department of Labor (U.S. Bureau of Labor Statistics, 2004). Improving the quality of child care available to all families, but particularly those at high risk, therefore must be treated as a critical social policy priority.

Exemplary in illustrating the effective use of existing resources for providing quality care for low-income preschoolers is Zigler's "school of the twenty-first century," a comprehensive program that is built into extant school systems (Finn-Stevenson & Zigler, 1999). In this program, public school buildings, which remain unoccupied

for large portions of the day and the calendar year, are used not only to house child care programs for children 3 years and older, but also to host regular support group meetings for parents. Information and referral networks also are developed in schools to help families make better use of the various existing services scattered across their communities, such as those offering counseling, physical health care, or night care for children. In the years ahead, it is critical that preventionists and social policy scholars increase the creative use of existing community resources in mobilizing protective influences to benefit different at-risk groups (Barrera & Prelow, 2000; Knitzer, 2000a, 2000b; Luthar, 1999; Pianta & Walsh, 1998).

Researchers have expanded their definitions of quality need to go beyond indices such as the caregiver-to-child ratio, physical space, and materials to stimulate learning, to consider also the emotional quality of caregiving children receive. It will be important to explore systematically the protective effects of such variables in early child care as the caregiver's personality characteristics, the sensitivity, warmth, and consistency in caregiving, and the quality of the relationship developed (Vandell, Dadisman, & Gallagher, 2000).

With regard to the relative effects of child care versus family characteristics, Shonkoff and Phillips (2000, p. 309) indicated, based on their review of the literature, that "when child care effects are examined net of parental effects on child outcomes, parent's behaviors and beliefs show substantially larger associations with their children's development than do any other features of the child care arrangement." Exemplifying this statement is evidence from the NICHD Early Child Care Research Network (2003), where the most consistent predictor of positive outcomes during the early school years was the sensitivity of mothers' behaviors observed across the infant, toddler, and preschool years (see also Vandell et al., 2000).

Turning to older children: K-12 schools can also bring substantial salutary effects to youth in at-risk circumstances (B. J. Feldman, Conger, & Burzette, 2004). There are several studies corroborating the protective functions of supportive relationships with teachers (e.g., Hamre & Pianta, 2001; NICHD Early Child Care Research Network, 2003; Reddy, Rhodes, & Mulhall, 2003). Assessing more than 3,000 teacher-child relationships, Howes and Ritchie (1999) demonstrated that in a sample of toddlers and preschoolers with difficult life circumstances, the quality of attachment with teachers was significantly related to measures of behavior problems as well as social competence with peers. Meehan, Hughes, and Cavell (2003) found that among a group of aggressive second- and third

graders, African American and Hispanic students benefited more than did Caucasian students from supportive relationships with their teachers. Noting that minority group students typically have lower access to positive relationships with teachers, the authors suggested that they could be more responsive than Caucasians to supportive teachers when such relationships are encountered (see also J. N. Hughes, Cavell, & Jackson, 1999). Similarly, among African American 7- to 15-year-olds from low-income, mother-headed households, Brody et al. (2002) demonstrated protective-stabilizing effects among children whose classrooms reflected organized, predictable environments in which students participated in procedures governing their behaviors. Furthermore, positive classrooms were beneficial even when parent-child relationships were compromised as well as vice versa, indicating unique, significant contributions from both contexts in which children and adolescents spend appreciable amounts of time (Brody et al., 2002; Way & Robinson, 2003).

These findings are entirely consistent with results of interventions targeting features of the school and classroom as well as the family. The Seattle Social Development Project is a case in point; this is a universal intervention designed to work with teachers, parents, and the children themselves to decrease children's problem behaviors. Evaluations have shown gains in several domains, including students' school performance, substance use, delinquency, and commitment to school and the quality of family management practices (Hawkins et al., 2003). Another large-scale, multifaceted school-based intervention is the FAST Track project (Conduct Problems Prevention Research Group, 2004), designed for children at risk for conduct disorders, designed to provide interventions at the levels of the family, child, classroom, peer group, and school setting. High-risk intervention children have shown some improvements in various social, emotional, and academic skills as rated by teachers as well as by parents (Conduct Problems Prevention Research Group, 2004).

Attachment-Based Interventions in Schools

There are many rigorously evaluated programs addressing structure and discipline in the classroom, but there are currently few programs built around the notion of strong attachments to teachers. This is surprising, given recurrent findings that a supportive relationship with adults is critical in resilience and that teachers can play a major socializing role (e.g., L. Chang, 2003; E. A. Skinner, Zimmer-Gembeck, & Connell, 1998; Wentzel, 2002). Writing from an attachment perspective, Robert Pianta (1999) has eloquently described the benefits that can de-

rive from close child-teacher relationships developed and then sustained for as long a period of time as feasible. Commenting on the neglect of attachment-based interventions in schools, he notes the important possibility of broadening the pool of adults in schools who might contribute to such preventive efforts, to go beyond school psychologists or counselors. Pianta argues that there are often enough adults in a given school building to provide some support to children who need it; to some degree, what is needed is creative reassigning of responsibilities and continuity in relationships forged. Thus, in Felner and colleagues' (2001) School Transition Environment Program (STEP), and its successor, the Project on High Performance Learning Communities, the role of homeroom teachers was changed such that they accepted responsibility for counseling and advisory functions and served as a consistent link between students, families, and the school.

Going still further, some have suggested involving not only subject or homeroom teachers but also other adults to whom students are naturally drawn. As Noam and Hermann (2002) note, some at-risk students may actually be inhibited about seeking support from their own teachers, perceiving them primarily as disciplinarians and evaluators of academic progress. Similarly, Luthar and Zelazo (2003) note that students often seek out, as confidants or mentors, diverse school-based adults ranging from sports coaches and music instructors to administrative and support staff (see also Hetherington, 1993). To the degree that such interactions are already occurring in schools, it could be useful to formalize the process to some degree. Adults likely to be most effective as informal mentors could be identified via student nominations (Luthar & Zelazo, 2003). Systematizing their efforts in this regard could be fostered by (1) using student nominations to identify informal mentors (Lindsey & Kalafat, 1998), (2) some creative reassigning of responsibilities, and (3) provision of in-service training and supervision (again, using resources already existing in schools and through collaborative arrangements with applied psychology or social work programs in local universities; see Felner et al., 2001; Luthar & Zelazo, 2003; Pianta, 1999; Pianta & Walsh, 1998).

Although not necessarily tested by the same rigorous designs involving randomized assignments and multiple sites, two programs have in fact attempted to use attachment-based interventions in schools with some promising results. One is Cowen's (Cowen et al., 1996) Primary Mental Health Project, focused on preventing mental health problems among elementary school children, and the second is Noam and colleagues' (Noam & Hermann, 2002) Responsive Advocacy for Life and Learning in Youth (RALLY),

designed for middle school students in high-risk environments. At the core of both interventions are strong relationships. Discussing intervention gains, Cowen and colleagues noted, "The existence of a warm, trusting associate-child relationship is the foundation on which significant attitudinal and behavioral change in children rests" (p. 92). The RALLY intervention is grounded in the core premise that "resilience cannot develop without the personal, interpersonal, and emotional dimensions inherent in relationships" (Noam & Hermann, 2002, p. 874).

Schneider and colleagues (2003) have suggested that children with low perceived containment—who do not believe in adults' capacities to enforce firm limits—and are therefore at risk for Conduct Disorder might actually be better served by interventions focusing on sustained, positive relationships rather than short-term disciplinary techniques designed to counter misbehavior. Similarly, in their literature review of school-based programs effective in fostering resilient outcomes, Forman and Kalafat (1998) emphasized the protective potential of caring adults who hold high expectations and convey positive feedback, school structures that foster the development of relationships between students and adults, and fostering relationships between the school, parents, and community. Accentuating such informal school-based support systems could be particularly critical for the wellness of at-risk junior high and high school students because they face schools that are increasingly impersonal, with diminishing supports infused in daily curricula, and because adolescents can be particularly reluctant to seek professionals to help with even the most serious of adjustment problems (Doll & Lyon, 1998; Eccles et al., 1993; Forman & Kalafat, 1998; Short, 2003).

In considering the enhanced use of school-based interventions in future years, a number of potential impediments must be considered carefully, significant among which is schools' overarching emphasis on developing literacy skills. Although there are in fact ongoing opportunities to foster good problem-solving skills and social competence (Doll & Lyon, 1998), Adelman and Taylor (1999, p. 138) caution, "Schools are not in the mental health business. Their mandate is to educate." To foster more inclusive thinking, the authors underscore that scientists must systematically disseminate evidence that children's psychological problems can substantially impede achievement of literacy goals, and conversely, that mental health services can help in reaching them (Adelman & Taylor, 2003). All major stakeholders—parents, teachers, school administrators, and legislators—are likely to be more receptive of interventions if they clearly understand the evidence that children with social-emotional problems are at elevated

risk for poor academic performance and eventually are at elevated risk for dropping out of school and subsequent problems in adulthood (National Institutes of Health, 2000; Noam & Hermann, 2002; Rones & Hoagwood, 2000; Short, 2003).

Another major impediment to the widespread use of schools to foster mental health has been interventionists' neglect of critical contextual factors. Ringeisen, Henderson, and Hoagwood (2003) argue that the children's mental health literature does encompass multiple evidence-based interventions (such as those previously cited here). In efforts to transfer interventions developed in laboratories to the school setting, however, there has been an unfortunate lack of attention to aspects of the school context that strongly affect intervention delivery (e.g., by involving teachers in the design and implementation of interventions). The third impediment is perhaps the most obvious one, that of burden: Resources are already stretched thin, particularly so in those schools that most need them. For example, it is estimated that the ratio of school psychologists or school social workers to students is about 1 : 2,500; for school counselors, the ratio is 1 : 1,000. Acknowledging these constraints, several authors have indicated that the most urgent task need of the day is not necessarily to provide more resources for mental health services in schools, but to use existing resources more prudently than they typically are used. We need movement away from individually based mental health service delivery to integrated models involving group- and classroom-based approaches, ongoing professional consultations for school personnel, and involvement of families and communities (Atkins, Graczyk, Frazier, & Abdul-Adil, 2003; Doll & Lyon, 1998; Felner et al., 2001; Hoagwood & Johnson, 2003).

Peers and Social Networks

Aside from adults at school, positive relationships with peers can also serve important ameliorative functions for at-risk children (Benard, 2004; Elder & Conger, 2000; Jackson & Warren, 2000). Among children of divorce, for example, a supportive relationship with a single friend may help to buffer children from the deleterious effects of marital disruption (Hetherington & Elmore, 2003; see also Bolger & Patterson, 2003). Other longitudinal research has shown that peer acceptance and friendships attenuated the association between aspects of family adversity and subsequent externalizing behaviors at the time of entry into elementary school and between fifth and seventh grades (Criss et al., 2002; Lansford, Criss, Pettit, Dodge, & Bates,

2003; Schwartz, Dodge, Pettit, & Bates, 2000). Findings such as these are viewed as reflecting three potential mechanisms: (1) the provision of "remedial" socializing contexts for skills not acquired in dysfunctional homes; (2) modification of parents' and children's negative behaviors by the more well-functioning peers and their parents; and (3) enhanced bonds with the social institution of the school (Lansford et al., 2003).

Intervention studies have also shown that peer-assisted learning can result in significant increases in achievement (Rohrbeck, Ginsburg-Block, Fantuzzo, & Miller, 2003), although there have been relatively few large-scale, randomized trials involving use of peers to promote outcomes. The potential in this regard is seen in Fantuzzo and colleagues' (1996) resilient peer treatment program, a peer-mediated classroom intervention involving pairing of socially withdrawn children with manifestly resilient peers in the classroom. In addition, several elementary and middle schools throughout the country tend to use peer mediation to reduce conflict and promoting positive behaviors (e.g., Johnson & Johnson, 2001; Smith & Daunic, 2002), but again, there is a need for more rigorous evaluations of their effectiveness. Underscoring the socializing potential of peer environments, Kupersmidt, Coie, and Howell (2004) advocate enhanced exploration of programs to prevent the spiraling of problems of aggressive children by promoting contacts between them and their more conventional peers.

Just as positive peer relationships can ameliorate effects of adversity, problems in this domain can exacerbate vulnerability: Children who have been rejected by their peers show relatively poor outcomes across multiple domains in later life, including internalizing problems, school dropout, and delinquency (Kupersmidt & Dodge, 2004). In a series of studies with longitudinal designs, social rejection was a consistent predictor of adolescent and adult criminality, sexual promiscuity, suicide, Schizophrenia, and substance use (McFadyen-Ketchum & Dodge, 1998). The combination of aggression and rejection spells particularly high risk for long-term adjustment outcomes (see Kupersmidt & Dodge, 2004).

Affiliation with deviant peers is a factor well known to exacerbate vulnerability among at-risk youth, particularly in relation to conduct problems and substance use. Among preadolescent children of substance-abusing fathers, affiliation with deviant peers was a robust predictor of child psychopathology (Moss, Lynch, Hardie, & Baron, 2002), as it is among adolescents experiencing stressful life experiences both within and outside the family (e.g., Barrera et al., 2002; Scaramella, Conger, Spoth, & Simons, 2002;

Tyler, Hoyt, Whitbeck, & Cauce, 2001). In the Great Smoky Mountains Study, data on 9- to 15-year-olds interviewed during the first three waves of this project showed that association with deviant peers, along with increasing levels of circulating testosterone, contributed to increases in conduct disorders with age. Furthermore, these associations were mediated primarily by increases in non-physically aggressive behaviors (Rowe, Maughan, Worthman, Costello, & Angold, 2004).

Dishion, McCord, and Poulin (1999) provided powerful evidence on the potentially iatrogenic effects of peer aggregation during early adolescence. These authors reviewed longitudinal research data showing that adolescent friendships can involve "deviancy training," which in turn predicts increases in delinquency, substance use, violence, and adult maladjustment. In addition, they presented findings from two experimentally controlled intervention studies showing that (1) as compared to control conditions, peer-group interventions actually increased adolescent problem behaviors and negative life outcomes in adulthood, and (2) high-risk youth were particularly vulnerable to such peer aggregations (i.e., more so than low-risk youth). Two developmental processes were discussed as possibly accounting for the powerful iatrogenic effects; the first involved active reinforcement for deviant behavior through laughter and social attention, and the second entailed the derivation of meaning and values that provided the cognitive basis for motivation to commit delinquent acts in the future.

The potential for such iatrogenic effects has often been discussed in relation to the ecology of urban poverty. In inner-city neighborhoods and schools, the peer culture tends to reflect the larger community, so that youth growing up in high-crime neighborhoods can be exposed to more delinquent peers than are youth in other environments (Cauce et al., 2003; Leventhal & Brooks-Gunn, 2000; Richters & Cicchetti, 1993). In turn, affiliation with delinquent peers exacerbates the risk for the development of adolescent behavior problems. Furthermore, the personal characteristics valued by peers in inner-city settings are often at odds with those endorsed more conventionally (Jarrett, 1999). For example, high peer popularity can be associated with disruptive, aggressive behaviors at school as well as low academic effort (Fordham & Ogbu, 1986; Luthar, 1995; Luthar & McMahon, 1996), ostensibly reflecting the lack of conviction in poor urban communities that conformity and application at school will actually result in long-term life successes.

Adding still further to the complexities of peer group effects, some have shown that influences of the inner-city

adolescent peer group can be beneficial in some spheres of adjustment, even as they are counterproductive in others. Seidman and Pedersen (2003), for example, reported that inner-city adolescents who were antisocial and highly engaged with friends were in fact at risk for delinquency. At the same time, they were notably less depressed than were comparison youth from the same background. There are also probably varying effects of high status in the wider peer group as opposed to support from close friends. Guttman, Sameroff, and Eccles (2002) found that levels of support from peers, as opposed to popularity with the wider peer group in previously discussed studies, was associated with higher math achievement test scores for high-risk adolescents, but not their lower-risk counterparts. The authors argued that peer support for academic success may in fact be limited for African American adolescents (Steinberg, Dornbusch, & Brown, 1992), but that among African American teens exposed to multiple risks, those who feel that they can depend on peers for help with problems fare better academically than their counterparts with low perceived peer supportiveness.

Aside from members of the peer group, relationships with informal mentors can serve critical protective functions. Evidence in this regard is seen in the Big Brothers Big Sisters of America (BBBSA) movement, a program that typically targets youth ages 6 to 18 years from single-parent homes. Service delivery is by volunteers who interact regularly with a youth in a one-to-one relationship, and supervision is provided on a monthly basis for the 1st year and on a quarterly basis subsequently. An evaluation of the program has shown that as compared to their non-participating peers, BBBSA youth were 46% less likely to initiate illegal drug use, 27% less likely to initiate alcohol use, and 52% less likely to skip school. They also fared substantially better on academic behavior and attitudes and had higher-quality relationships with their parents or guardians as well as their peers (Tierney, Grossman, & Resch, 1995).

With regard to mediators and moderators, Rhodes, Grossman, and Resch (2000) tested a conceptual model in which the effects of mentoring were mediated through improvements in parental relationships. The study included almost 1,000 youth, randomly assigned to BBBSA or a control group, and questions were administered at baseline and 18 months later. Results indicated that improved family relations did in fact mediate mentoring effects. In another study, Grossman and Rhodes (2002) found that duration of the relationship was a significant moderator variable. Adolescents in relationships lasting a year or longer reported

the largest number of improvements, with progressively fewer gains (and sometimes even decrements) seen with reductions in relationship length.

Salutary socialization experiences can derive from religious affiliation as well (Elder & Conger, 2000; Pearce, Jones, Schwab-Stone, & Ruchkin, 2003). Studies by Miller and her colleagues have demonstrated that religious adolescents have relatively lower risk for problems such as depression and substance use (e.g., Miller, Davies, & Greenwald, 2000; Miller & Gur, 2002). Mechanisms posited include indirect effects of primary socialization (in that religion shapes the primary socialization sources, comprising parents, peers, and school) as well as direct ones (aiding in the adolescent's search for meaning, purpose, and identity in life).

The benefits of community supports to at-risk children are paralleled by those to their parents: Parents with informal social support networks show better psychological well-being and positive parenting and fewer negative parenting practices (Belsky, 1980; Burchinal et al., 1996; R. D. Taylor et al., 1993). Among inner-city mothers, those with high levels of perceived support displayed relatively few depressive symptoms, experienced less negativity about the parental role, and used less punishment (McLoyd, Jayaratne, Ceballo, & Borquez, 1994). By the same token, feelings of social isolation and loneliness tend to characterize low-SES parents who are neglectful of their children more than those who are not (Luthar, 1999).

Perceptions of social support may be more critical for disadvantaged individuals than support actually used (Berman, Kurtines, Silverman, & Serafini, 1996). Actual receipt of help from others—for example, with child care—benefited parents from different economic backgrounds, but expectations of adequate support in crises were more advantageous for low-income families than for others (Hashima & Amato, 1994). Given the paucity of resources and the multiplicity of life stressors among parents who contend with conditions of serious economic disadvantage, convictions that help will be forthcoming when needed may be particularly comforting to them.

Indirect benefits to children via support received by parents are also evident in research on interventions (e.g., Luthar & Suchman, 2000). In the Chicago Parent-Child Project, for example, many of the benefits deriving from this program were mediated by parents' involvement in children's education and school (Reynolds, 2000; Reynolds & Ou, 2003), probably reflecting improvements in parenting practices and attitudes, as well as enhanced family support. As noted earlier, in Yoshikawa's (1994) review of early intervention programs successful in reducing long-

term delinquency, comprehensive support to parents constituted a key ingredient.

Support to parents via religious communities can also be beneficial. Brody, Stoneman, and Flor (1996) showed that among rural African American families, relatively high formal religiosity was linked to more cohesive and less conflictual family relationships. Associations such as these might reflect, in part, the connectedness and social supports experienced by those who attend church regularly, as church attendance provides a place for families to gather and socialize (Brody et al., 1996). In addition, intrapersonal processes might be implicated, such as reliance on relatively effective coping strategies. Kendler, Gardner, and Prescott (1997) reported, based on twin study data, that adults with high personal religiosity reflected comparatively low susceptibility to the depressogenic levels of stressful life events; they also reported lower levels of alcohol and nicotine use compared to others. Among parents who had lost an infant to Sudden Infant Death Syndrome, those high on religious participation and importance showed less distress than others, and these effects were mediated by two dimensions of coping: cognitive processing of the loss and finding meaning in the death (McIntosh, Silver, & Wortman, 1993). Similarly, among elderly women who had suffered hip fractures, those who were more religious had better physical and psychological coping than did others (Pressman, Lyons, Larson, & Strain, 1990).

The connotations of religiousness are not invariably positive, however; in fact, it can sometimes exacerbate vulnerability. Among women (but not men) who had been depressed as children, personal religiousness was found to pose as much as a twofold increase in risk for depression in adulthood (Miller, Weissman, Gur, & Greenwald, 2002). The authors suggest that childhood depressive symptoms such as guilt, low self-worth, and excessive self-blame (all common features of female depression) can sometimes distort religious messages emphasizing altruism, empathy, and other-centeredness, leading some women to become excessively submissive, self-depriving, and lacking in self-expression. Furthermore, Garcia Coll and Vasquez García (1995) have argued that strong beliefs in the supernatural may sometimes take the form of fatalism, and if at-risk youth and families come to believe that nothing can be done to improve one's lot in life, this can create formidable barriers in improving the overall quality of their lives.

Neighborhoods

Moving on from the relatively proximal extrafamilial contexts of school, peers, and interpersonal supports to those

more distal, aspects of the community may also play an important role in buffering risk for children (Garbarino, Hammond, Mercy, & Yung, 2004; Gorman-Smith & Tolan, 2003; Sampson, 2001). Particularly important are social organization processes in the neighborhood (Sampson et al., 1997; Wilson, 2003), which involve features such as high levels of cohesion, a sense of belonging to the community, supervision of youth by community adults, and high participation in local organizations. Such neighborhood social processes can help buffer the impact of structural characteristics of the community (e.g., poverty, violence) either by affecting parents' behaviors or directly benefiting children themselves (Furstenberg et al., 1999; Leventhal & Brooks-Gunn, 2000; Sampson, 2001). To illustrate the former, Mahoney and Magnusson (2001) found that among at-risk youth, fathers' involvement in community activities in late childhood was associated with significantly lower risk for persistent criminal involvement over time. These findings were seen as possibly reflecting the effects of more conventional values of fathers who were involved in community activities, their relatively greater personal resources, or their generally higher levels of involvement in their sons' lives. Direct benefits to children are seen in Gorman-Smith and Tolan's (2003) findings that when inner-city families are lacking in warmth and closeness, children's vulnerability can be reduced somewhat if they feel a sense of belonging and support in the neighborhood.

Whereas extracurricular activity involvement is widely believed to confer protective functions, the type of benefit depends, to some extent, on the degree of structure of the activities. Research by Mahoney (2000) showed that among pre- and early adolescent children manifesting multiple adjustment problems, involvement in school extracurricular activities was linked with reduced rates of early dropout and criminal arrest over time. Results of another study, however, indicated that it was only participation in structured leisure activities that reduced risk for antisocial behavior; when structure was low (as in youth recreation centers), risks for deviant peer relations and antisocial behaviors were actually heightened (Mahoney & Stattin, 2000).

Youth-serving community organizations can directly provide protective functions to low-income youth, but the number that actually deliver this in contemporary society is woefully inadequate. Just as quality day care is rarely obtainable by those who need it the most, so are quality youth organizations rare in those neighborhoods that most need them, where economic and political resources are low and social disorganization is high (Cauce et al., 2003). This dearth of institutional services, along with low resources in schools, results in a lack of attractive, organized, and

positive afterschool activities for youth, leaving them open to the allure of illegal activities with peers and adults in the community (Luthar & Burack, 2000; Seidman & Pederesen, 2003).

There have been few neighborhood-level interventions thus far that have been focused on children's well-being (Leventhal & Brooks-Gunn, 2000), yet promising efforts are seen in Tolan and colleagues' (2004) *Schools and Families Educating Children* (SAFE Children) intervention. This preventive program is focused on promoting strong family relationships and developing support networks in the neighborhood, with attention also to children's academic functioning. Intervention families have shown improvements in parents' functioning and in children's academic performance, with gains most pronounced among those who, at the outset, manifested the highest levels of disturbance (Tolan et al., 2004).

Based on their own experiences, Gorman-Smith and Tolan (2003) note that in designing future interventions based at the neighborhood level, two interrelated considerations are critical. The first is that they should involve constituent groups as far as possible, and the second is that (as with families), they should strive to promote benefits that can be sustained by recipients over time. Gorman-Smith and Tolan also point to the promise of community efforts involving coalitions of local groups and agencies (such as police and faith-based organizations) in addressing risks specifically associated with urban poverty (e.g., initiatives to inhibit illegal gun trade).

Finally, among adults, relocation out of at-risk communities can be beneficial by providing major changes in life opportunities or in people's cognitive set and self-views (Werner & Smith, 1992). Movement toward relatively positive trajectories has been shown, for example, with respect to army experiences for low-income youth prone to delinquency (Laub & Sampson, 2003; Sampson & Laub, 1996). Among low-income children who had poor grades and self-inadequacy, those who entered military service relatively early showed more positive outcomes in terms of completing their education, getting married, and having their first child later than did nonveterans (Elder, 1986).

Individual Attributes: Malleability in Contexts

In overviewing the triad of vulnerability and protective processes in resilience, it has been argued that children's own attributes should be considered after aspects of their family and community for three critical reasons (see Luthar & Zelazo, 2003). From a basic research perspective, numerous studies, described in some detail in discussions

that follow, have shown that many positive child attributes are themselves often dependent on processes in the proximal and distal environments. From an applied perspective, it is logical that interventions to foster resilience should focus less on what young children are able to do for themselves and more on what adults must do to bolster the children's own efforts. From a policy perspective, to place primary emphasis on child attributes could carry the risk that public debate will shift away from the major environmental risks that affect children, leading to decreased allocation of resources to ameliorate these risks (see Luthar et al., 2000a; Luthar & Zelazo, 2003). It is these due to considerations, rather than any devaluing of children's own strengths, that the emphasis is placed on families and communities in transaction with the children rather than the other way around.¹

To underscore the perils of overemphasizing children's own attributes, we begin this section by presenting evidence on the malleability of some of the most commonly cited *protective child attributes*, starting with intelligence (probably the single most often mentioned asset). Studies on diverse risk groups show that individuals with high IQ tend to fare better than others (Luthar, 2003; Masten, 2001). At the same time, evidence of environmental influence is seen in Sameroff and colleagues' (Sameroff, Seifer, Zax, & Barocas, 1987) findings almost 2 decades ago that children facing no environmental risks scored more than 30 points higher than children with eight or nine risk factors. No preschoolers in the zero-risk group had an IQ below 85, whereas 26% of those in the high-risk group did.

Since then, others have shown that disturbances in parents' functioning can affect child intelligence. A twin study by Koenen, Moffitt, Caspi, Taylor, and Purcell (2003) showed that among 5-year-old children, those exposed to high amounts of domestic violence had an IQ that was 8 points lower, on average, than the IQ of children not exposed to domestic violence. Furthermore, domestic violence accounted for significant variation in IQs even after considering possible genetic effects and externalizing and internalizing problems that could impair performance on

standardized tests. Similarly, maternal depression has been associated with relatively low child cognitive functioning both in the postpartum period (Murray, 1992; Sharp et al., 1995) and in the preschool years (NICHD, 1999; see also Cicchetti et al., 2000).

Powerful testimony on this issue lies in work by Rutter, O'Connor, and their colleagues, on adoptees from Romanian orphanages. Caregiving conditions in these orphanages ranged from poor to appalling: Infants were typically confined to cots, there was no personalized caregiving and few toys, feeding often occurred via propped-up bottles, and washing was done by hosing the babies down (Rutter & the English and Romanian Adoptees Study Team, 1998). When these children entered into adoptive families in the United Kingdom, they had mean cognitive functioning scores in the mentally retarded range. However, longitudinal evaluations showed catch-up effects, in that babies who were adopted by 2 years of age by families in the United Kingdom lost their profound early deficits, and by the age of 4 came to show near-average developmental status.

In terms of underlying mechanisms, environmental deprivation may lead to cognitive deficits because of lack of appropriate stimulation and even adverse effects on brain development. Depressed and psychologically withdrawn caregivers, for example, can provide limited stimulation for the development of cognitive skills and expressive language, and deficits in the mother-child relationship can constrain the child's developing sense of self-efficacy and agency, in turn inhibiting her active exploration of the environment (Cicchetti et al., 2000). Biologically, studies have shown that stress generates high levels of catecholamines and cortisol, and chronic activation of the stress response can result in the death of neurons in specific brain regions, with these effects most profound during early childhood, when neuroplasticity is high (Cicchetti & Walker, 2003; DeBellis, 2001; DeBellis et al., 1999; Sanchez, Ladd, & Plotsky, 2001). Results of animal studies clearly establish that early enriched versus deprived environments connote substantial differences in animals' neurochemical, physiological, and neuroanatomical functioning, with the last including variations in the weight of the brain and structural modifications of the cerebellar cortex (Curtis & Nelson, 2003).

Discussions on intelligence thus far have been focused on periods early in development, and one might argue that high IQ would be more powerful in resilience later in development; though probably true, the evidence is not unequivocal even at older ages. Up through middle childhood, it does seem that bright children tend to show stability in everyday competence despite increasing levels

¹ A parallel approach is evident in the Search Institute's listing of 40 developmental assets. The list begins with the *external assets*, and noted first are dimensions of support, including the categories of family support, positive family communication, other adult relationships, caring neighborhoods, and caring school climates. *Internal assets* are the second 20 items on the list, subsumed in categories such as commitment to learning, positive values, and positive identity.

of life stress (e.g., Garmezy et al., 1984; Masten, 2001). On the other hand, among three different samples of low-income adolescents, intelligence was not found to be protective; to the contrary, there were suggestions that bright youth may be more sensitive than others to negative environmental forces (Gutman et al., 2003; Luthar, 1991; Luthar & Ripple, 1994). In other words, intelligent adolescents fared far better at school than did less intelligent ones when life stress levels were low, but when stress was high, they lost much of this advantage and showed competence levels similar to those of their less intelligent counterparts. More striking, Fiedler (1995) found that high IQ adults showed leadership success under conditions of low stress, but that when stress was high, IQ was *inversely* correlated with leadership success.

Findings such as these have been viewed as suggesting that the manifest benefits of innate intelligence vary depending on aspects of the proximal environment. In areas of concentrated poverty, where conventional means of achieving self-worth (e.g., good grades, productive employment) are generally scarce, for example, intelligent and creative teenagers may use their talents in ways that bring more immediate gains, such as illegal entrepreneurship, rather than through striving for excellence at school (Gutman et al., 2003; Luthar, 1991; Richters & Cicchetti, 1993). Freitas and Downey (1998) cite research showing such patterns among adult women who were incarcerated; among recidivists, many personal attributes commonly seen as protective in nature were identified as actually aiding them in their criminal activities.

The previously described evidence on intelligence is paralleled by similar evidence on temperament, also shown to confer protection against stress (e.g., Mendez, Fantuzzo, & Cicchetti, 2002; Murry, Bynum, Brody, Willert, & Stephens, 2001). Benefits have been found in relation to not only psychological and behavioral but also biological outcomes. To illustrate, children low on behavioral inhibition may react less to stress than others, as suggested by evidence of resting right frontal EEG activation among inhibited children (Calkins & Fox, 2002); as noted earlier, this pattern is linked with tendencies to respond to stressful events with negative affect or depressive symptoms (Curtis & Cicchetti, 2003).

Whereas temperamental differences can be seen as early as 4 months of age and show continuity over early childhood (e.g., Kagan, Snidman, & Arcus, 1998), both the manifestation and ramifications of temperament can be modified by environmental features. During the preschool years, for example, children show differences in terms of

shyness versus extraversion, as well as the tendency to feel negative emotions more or less deeply (Rothbart & Jones, 1998), and the external manifestations of both these dimensions can be modulated by effortful control. As Rutter (2000) has noted, scientists long ago moved past the point of misleading assumptions that “constitutional” factors are unalterable; whereas some children do have a tendency to be more impulsive or oppositional than others, their interactions with the world contribute to determining the behavioral conformity they display. In a similar vein, some children are temperamentally more exuberant than others, and some feel negative emotions more intensely than do others, but the external manifestation of these emotions and whether they lead to rejection by peers depends on the degree to which they can modulate their emotions (Fabes et al., 1999; Rubin, Coplan, Fox, & Calkins, 1995). And children’s abilities to modulate or inhibit the expression of emotions depend, as described in the paragraphs that follow, on the nature of their interpersonal relationships, particularly those early in life.

Several studies have established the protective effects of self-regulation from early childhood onward (see Shonkoff & Phillips, 2000). Among low-income children, emotion regulation at the age of 3½ was related to self-control on entry into first grade (Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002), and those with low emotional knowledge at first grade showed significant increases in internalizing symptoms over the next 4 years (Fine, Izard, Mostow, Trentacosta, & Ackerman, 2003). These findings suggest that among children just entering school, those who find it difficult to interpret others’ emotions may get into a cycle where dysfunctional social exchanges lead to isolation and thus sadness, and these emotions in turn jeopardize future interactions with others. Among adolescents in low-income families, Buckner et al. (2003) found that good self-regulation contributed to resilience—good mental health and emotional well-being—even after considering self-esteem and nonverbal intelligence. Even perceived self-efficacy to regulate positive and negative affect is related to adolescents’ beliefs that they can manage academic, transgressive, and empathic aspects of their lives, with these forms of perceived self-efficacy, in turn, related to later levels of depression, delinquency, and prosocial behaviors (Bandura, Caprara, Barbaranelli, Gerbino, & Pastorelli, 2003).

As suggested earlier, self-regulation itself depends squarely on relationships; in point of fact, children’s compliance within the mother-child dyad is the first sign of internalizing adults’ rules (R. Feldman, Greenbaum, &

Yirmiya, 1999; Kochanska, 1997; Kochanska, Coy, & Murray, 2001; Stifter, Spinrad, & Braungart-Rieker, 1999). As Shonkoff and Phillips (2000, p. 121) emphasize:

It is clear at this point that the various components of active, internally guided regulation of attention, behavior, and emotion emerge . . . in the context of caregiving relationships that explicitly guide the child from her dependence on adults to regulate virtually every aspect of functioning to gradually taking over and self-regulating her own behaviors and feelings in one aspect of her life after another.

In their study of 90 toddlers, R. Feldman and Klein (2003) showed that compliance to parents in child care centers was associated with parents' sensitivity and philosophy. Among young boys in low-income families, secure attachment to mother and positive maternal control at the age of 1½ years predicted effectiveness of emotion regulation at the age of 3½, and this in turn was related to capacities for self-control on entry into first grade (Gilliom et al., 2002). Finding that self-regulation distinguished manifestly resilient low-income adolescents from others, Buckner and colleagues (2003) noted that this capacity is itself shaped by teenagers' relationships in the family.

Aside from self-regulation, individuals' propensities to cope effectively with challenges also rests on "meaning making"—phenomenological interpretations of events in their lives (e.g., Beardslee, 2002; Hauser, 1999; Noam & Hermann, 2002)—and this, too, is shaped by the environment as demonstrated in Spencer's (1999; Spencer et al., 2003) phenomenological variant of ecological systems theory (PVEST). At the core of PVEST lie identity processes, which define how adolescents view themselves within and between their various contexts of development. Emerging identities, however, are themselves conceptualized as emerging within the framework of contextual forces that potentially confer vulnerability (e.g., poverty or racial subordination) and net stress engagement, which is the individual's actual experiences of both risks experienced and support systems drawn on. Depending on the nature and balance of these risks and supports, the individual develops reactive coping methods, which in turn shape emergent identities and, eventually, long-term life stage-specific coping outcomes. A particularly attractive feature of Spencer's PVEST theory is the careful articulation of policy implications. She specifically underscores the need for policymakers to recognize that "problem behaviors" cannot be conceptualized as stemming simply from a child's own faulty coping processes or aberrant meaning making, for these often are products of uncontrollable contextual forces. Accordingly, interventions should address multiple

levels of the environment rather than focusing primarily on the child labeled as being at risk.

There is similar evidence showing that many other child attributes commonly labeled as protective factors can themselves be shaped substantially by the environment. Self-efficacy, as Maddux (2002) notes, is strongly influenced by the degree to which adults encourage or hinder the child's attempts at manipulation and control (Bandura, 1997). Self-esteem can be protective for at-risk children but is itself affected by parental warmth (Sandler et al., 2003). Internal locus of control is commonly cited as being protective (e.g., Capella & Weinstein, 2001), and Bolger and Patterson (2003) showed that early onset of maltreatment reduces the chances that children are able to maintain internality of control. Other research has shown that when teachers are perceived as cold and inconsistent, this progressively erodes students' convictions that they can produce their own successes and avoid failures (E. A. Skinner et al., 1998).

The preceding examples resonate with recommendations from resilience researchers for caution against inordinately emphasizing the importance of protective child attributes that are themselves malleable by the environment (see Luthar et al., 2000a; Yates et al., 2003); at the same time, there are several other caveats that warrant attention. First, as we noted at the outset, prior discussions are not intended to detract in any way from children's own strengths. Rather, the effort is (1) to circumvent any misguided blaming of the victim that might stem from an emphasis on child traits, and (2) concomitantly, to underscore the need for policies alleviating the contextual risks facing many youth. Second, there is no suggestion that personal attributes do little for resilience in any absolute sense. In fact, bright children likely fare better than others in many ways; the point here is simply that even these youth may not realize their full potential if they continually contend with environmental assaults. Third, the relative salience of personal versus others' attributes obviously shifts over time, with young children's well-being being more dependant on the emotional sustenance they receive than is the well-being of adults. Fourth, our arguments are not intended to minimize the possibility that children's attributes can themselves exert effects on the environment, for example, by eliciting different reactions from adults (e.g., Laird, Pettit, Bates, & Dodge, 2003; MacKinnon-Lewis, Lamb, Hattie, & Baradaran, 2001). From an intervention standpoint, however, applied scientists are less likely to "change" a young child to evoke positive feelings in parents and teachers than to help adults behave in ways that evoke positive reactions in the child. In the words of Shonkoff and Miesels (2000, p. 123):

For children whose problems do not fall within the clinical range, early interventions to address regulatory behavior focused on “fixing” the environment . . . warrant serious attention to balance the current focus on “fixing” the child. It is also clear that focusing on young children’s relationships with adults and peers is a promising and complementary, yet poorly exploited approach.

In a related vein, we do not imply in any way that programs addressing children’s own competencies do not work, merely that the successful ones focus not only on the child, but also on the environment, by working, for example, with teachers and parents (Shonkoff & Phillips, 2000; Zigler & Styfco, 2001). This is true even among children well past the infancy and preschool years, as is exemplified in research by Sandler and colleagues. Working with school-age children of divorce, these investigators designed an intervention with separate programs for mothers and for children. Experimentally induced change in maternal warmth did in fact lead to a reduction in children’s mental health problems, whereas working with children’s coping alone did not (Sandler et al., 2003; see also Maton, Schellenbach, Leadbeater, & Solarz, 2004).

Other Individual Assets: Future Research Needs

The personal characteristics already discussed—intelligence, easygoing temperament, self-regulation, self-esteem, self-efficacy, and internal locus of control—are commonly cited in the resilience literature (see Masten, 2001), but there are many others that warrant further empirical attention. Among these are practical and emotional intelligence. Sternberg and Grigorenko (2000, p. 215) have defined practical intelligence as “intelligence as it applies in everyday life in adaptation to, shaping of, and selection of environments”; it is complementary to but distinct from crystallized intelligence as measured by IQ tests. The importance of this construct is evident in studies of children and adults. In a village in Kenya, Sternberg and his colleagues (2001) found that children who had learned how to use natural herbal medicines to cure their various ailments were viewed by the community as both intelligent and adaptive. However, this aspect of practical intelligence was negatively correlated with conventional tests of crystallized abilities. Similarly, among adults, assemblers in milk-processing plants use complex strategies for combining partially filled cases of milk to minimize the number of moves needed to fill an order (e.g., Scribner, 1984). The order-filling performance of the assemblers was unrelated to intelligence test scores or arithmetic test scores and grades (Sternberg et al., 2001). In future research, greater

attention is clearly needed to practical intelligence as a protective factor across different risk conditions and in relation to different outcomes.

Emotional intelligence, as conceptualized by Mayer, Salovey, and their colleagues (Mayer, Salovey, Caruso, & Sitarenios, 2003; Salovey, Mayer, Caruso, & Lopes, 2003), is the ability to perceive and express emotions, to understand and use them, and to manage them to foster personal growth. The construct has four dimensions: (1) perceiving emotion, (2) using emotion to facilitate thought, (3) understanding emotion, and (4) managing emotion. In terms of its potential association with resilience, emotional intelligence is in fact a central construct in school-based initiatives aimed at promoting social-emotional learning in children (see Elias, Arnold, & Hussey, 2003; Greenberg et al., 2003). Among adolescents, furthermore, researchers have shown that this construct is linked with relatively low likelihood of smoking cigarettes and drinking alcohol (Trinidad & Johnson, 2002) and, following the major life transition to beginning college, with greater likelihood of attaining high academic grades (Parker, Summerfeldt, Hogan, & Majeski, 2004). In adulthood, emotional intelligence has been associated with relatively positive health outcomes, possibly reflecting psychophysiological responses to stress (e.g., relatively low cortisol and blood pressure responses to acute laboratory stressors; Salovey, Stroud, Woolery, & Epel, 2002).

In future research on intelligence and resilience, it is important not only to disentangle the contributions of practical, emotional, and crystallized intelligence, but also to move from focusing on discrete skills or particular milestones to the *underlying processes and functional capacities* that underlie skills that span multiple domains (Cicchetti & Wagner, 1990). Rather than relying on standardized IQ or achievement tests, for example, it will be most useful to assess the underlying capacities that make it possible for children to learn, such as the development of different problem-solving strategies, the ability to generalize learning across situations, and the unfolding of high motivation to explore and master new challenges (Shonkoff & Phillips, 2000).

Aside from dimensions of intelligence, studies with adults have shown the importance to resilient adaptation of developmental maturity, as reflected in the types of defense mechanisms typically used. Vaillant (2000) has noted that the more mature defenses—such as altruism, suppression, humor, anticipation, and sublimation—tend to be linked with relatively positive outcomes among individuals at risk and, at the same time, are relatively independent of social class, education, and IQ. In a long-term follow-up

study of 73 14-year-old inner-city boys with low IQ and a socioeconomically matched group with an average IQ of 115, Vaillant and Davis (2000) found that at the age of 65, half of the low-IQ men were comparable to the high-IQ group in terms of their own income and their children's level of education. These resilient low-IQ men were far more likely than their low-IQ, poor-outcome counterparts to use predominantly adaptive defenses, with the latter group more often using maladaptive defenses such as turning against the self, projection, and fantasy.

Potentially counterintuitive findings on the role of defenses in resilience stem from research on bereavement. Whereas repressive coping is generally viewed as maladaptive, research by Bonanno and colleagues suggests that it can foster resilience in the face of bereavement, as defined by the maintenance of relatively stable, healthy levels of psychological and physical functioning following the loss (see Bonanno, 2004). Studies by this group have shown that among bereaved individuals, repressors manifested relatively little grief or distress at any point across 5 years of bereavement. Among victims of childhood sexual abuse, similarly, repressors were less likely to voluntarily disclose their abuse when provided the opportunity to do so, but they also showed better adjustment than others (Bonanno, Noll, Putnam, O'Neill, & Trickett, 2003). Counter to psychodynamic emphases on the importance of working through negative emotions, therefore, Bonanno's literature review indicates that interventions emphasizing grief work can be not just ineffective but sometimes even deleterious.

Of particular importance, the effects of talking about grief might vary with developmental status; unlike bereaved adults, children may benefit significantly from being encouraged to talk about their loss. In research by Sandler and his colleagues (2003), bereaved children who talked about their feelings with family members had lower rates of mental health problems, whereas inhibition of emotional expression was associated with higher rates of internalizing and externalizing problems both cross-sectionally and prospectively. Differences in findings between children and adults may partly reflect children's more limited cognitive understanding of death (i.e., in terms of comprehending its finality), so that speaking about this could be generally helpful for them. On the other hand, for adults, continuing to talk about the loss could approach Nolen-Hoeksema's (2001) notion of rumination, which can compromise mental health. Another factor underlying the differences between studies might be variations in definitions of repression or inhibition of emotions. Sandler and colleagues note that they assessed children's

efforts to actively hide or inhibit their grief, whereas in many adult bereavement studies, repression was defined not in terms of deliberate efforts to inhibit affect, but in terms of discrepancies between autonomic arousal and verbal expression of distress.

Complex associations involving developmental maturity are also evident in findings on ego development, in that it is generally associated with positive adjustment but can also signal relatively keen sensitivity to distress. As conceptualized by Loevinger (1976), ego development refers to a "master" trait reflecting character development, which is related to various aspects of cognitive and interpersonal development, but that represents more than any of them considered individually. High levels of ego development attenuate risk for psychopathology in general and also among at-risk individuals (see Westenberg, Blasi, & Cohn, 1998). To illustrate, high ego development was linked with better coping strategies and fewer symptoms among psychiatrically hospitalized 12- to 16-year-olds (Recklitis & Noam, 1999) and with apparently lower reactivity to negative life events among inner-city youth (Luthar, 1991). Among substance-abusing mothers, those at high developmental levels were observed to have relatively positive interactions with their 1-month-old infant (Fineman, Beckwith, Howard, & Espinosa, 1997); among elderly women (75 to 103 years) living in long-term care facilities, higher versus lower levels of ego development showed links with affirming, negating, and despairing styles of reminiscence, in that order (Beaton, 1991).

As with intelligence, however, high levels of ego development are not necessarily an unmitigated blessing; as Noam (1998) has argued, higher developmental levels imply not just greater maturity but also greater complexity, so that individuals at high levels may manifest more complex problems. In a similar vein, Luthar and colleagues (2001) argued that among mothers who admitted to having "socially unacceptable" adjustment problems, such as uncontrolled displays of anger, those at high levels of ego development (being more introspective and self-critical) would suffer greater setbacks than others. Results were consistent with this reasoning, suggesting that the complexity and introspection characteristic of high developmental levels may be advantageous in general, but once disturbing problems have set in, introspection may come to take the form of counterproductive rumination or guilt.

Wolin and Wolin's (1993) definition of resilience encompasses a collection of several protective personal attributes. Their definition refers to the capacity to bounce back, to withstand hardship and to repair oneself, and is

based on the following elements: (1) insight, or asking difficult questions and giving honest answers; (2) independence, or distancing emotionally and physically from the sources of trouble in one's life; (3) relationships, or making fulfilling connections to others; (4) initiative, or taking charge of problems; (5) creativity, or using imagination and expressing oneself; (6) humor, or finding the humor even in difficult circumstances; and (7) morality, or acting on the basis of a conscience.

The protective potential of such constellations of attributes also has been demonstrated by Hauser, Allen, and their colleagues in narrative analyses in their long-term study of individuals psychiatrically hospitalized as adolescents (e.g., Allen et al., 1994, 1996). Hauser (1999) reported on a subgroup of these youth who seemed resilient as individuals; they had relatively high scores on multiple competence dimensions (e.g., relationship closeness and ego development) and low scores on several domains of psychopathology (crime and hard drug use). In-depth interviews revealed five major protective attributes: (1) self-reflection or high awareness of their feelings and thoughts; (2) self-efficacy, or agency in making conscious choices about their lives; (3) self-complexity in recognizing multiple facets to different situations; (4) persistence and ambition in education and careers; and (5) self-esteem that, on balance, was tipped more toward positive than negative self-views.

Beardslee (2002) has reported similar protective effects in his work with adolescent children of depressed parents. Resilient youth were aware of what they were facing—they recognized the parents' illness, knew that they were not responsible for it, and saw themselves as separate from their parents. In addition, they were able to put this experience in words and could articulate some strategies to offset the effects of the illness on them, for example, by forging nurturing relationships with adults outside the family. Among inner-city youth, Noam and Hermann (2002) noted the protective potential of both insight and the capacity to use symptoms and problems to motivate themselves toward positive change.

Of the various social-cognitive constructs linked with resilience, an intriguing one identified in the adult literature is benefit finding: the ability to see benefits in traumatic events. Among bereaved individuals, for example, Davis and colleagues (1998) found that 6 months after they had lost a loved one, as many as 73% of participants reported that they had experienced something positive, such as strengthened relationships with others, personal growth, and a new perspective on life. Furthermore, this capacity

for benefit finding uniquely predicted distress several months later. Similar trends were cited in a study of mothers whose infants were in neonatal intensive care units; again, three quarters of the participants indicated at least one benefit from the child's hospitalization experience (Affleck et al., 1991). Obviously, such benefit finding has greater potential to help with single or discrete traumatic events than with stressors that are ongoing, over time, from the external environment; they are also likely to be more useful for individuals capable of formal operational thought than children who think more concretely.

Empathy and altruism are two other attributes that can confer benefits to individuals facing adversities; both have been highlighted in the emerging positive psychology movement (e.g., Masten & Reed, 2002; Zhou, Valiente, & Eisenberg, 2003). In families with a depressed parent, Beardslee (2002) found that resilient youth had a well-developed capacity to see things from others' point of view and to think about their needs. Feeling useful and important to someone can also be critically important for one's own sense of well-being (Elder & Conger, 2000; Werner & Smith, 1992); the Search Institute (2004) lists several related positive values, such as caring for others, standing up for social justice, and involvement in service to others, among their 40 assets for healthy development.

High self-esteem can be protective, as feeling positive about ones' capabilities provides strength in coping with adversities, but frequently, there are complexities in associations involving self-views. As Bandura et al. (2003) showed, high perceived empathic self-efficacy among adolescents was related to high prosocial behavior and less delinquency among both males and females, but among the latter, was also related to depressive problems, possibly reflecting girls' greater tendencies to vicariously experience the distress of others and their relatively low sense of efficacy to manage their own negative affect. Similarly, unrealistic, overly positive views of oneself—self-enhancement—are often maladaptive, for example, in terms of evoking dislike from others (Paulhus, 1998). At the same time, self-enhancers can fare better than others in the face of serious trauma, when threats to the self are most salient. Among bereaved adults, self-enhancers showed better adjustment than others in terms of ratings by themselves, their close friends, and mental health professionals (Bonanno, 2004).

Harter's (2002) recent work suggests the value of another interesting construct that warrants attention: personal authenticity. This construct involves owning one's personal thoughts and emotions and acting in accord with

these (captured, respectively, by the injunctions “Know thyself” and “To thine own self be true”). Encompassing as it does integration across multiple selves, this construct may be particularly prominent, for example, in the adjustment of immigrant youth, who often face differing expectations at home and in the mainstream culture of public schools. Along with forces such as discrimination, language barriers, and conflicts between subcultural and mainstream value systems, this may affect their psychological adjustment.

Tendencies to use positive emotions can also help offset the effects of loss by quieting or undoing negative emotion and by increasing support from important people in the environment. Among bereaved individuals, for example, those who exhibited genuine laughs and smiles when speaking about a loved one recently lost manifested better adjustment, as rated by different respondents (Bonanno, 2004). The field of positive psychology has pointed to several other personal attributes that warrant further examination as potential correlates of resilience in the face of not only bereavement but other risks. Among people in general, positive outcomes have been found among people with high levels of hope, optimism, and “flow” (Snyder & Lopez, 2002; S. E. Taylor, Kemeny, Reed, Bower, & Gruenewald, 2000); all of these attributes also may be beneficial for individuals who contend with adverse life conditions across the developmental span.

SUMMARY OF EVIDENCE AND FUTURE DIRECTIONS: RECONCEPTUALIZING RESILIENCE

In concluding this chapter, the evidence reviewed from almost half a century of work on resilience is briefly summarized. Along with major findings from the literature, directions for future research and interventions are delineated.

The first major take-home message is this: Resilience rests, fundamentally, on relationships. The desire to belong is a basic human need, and positive connections with others lie at the very core of psychological development; strong, supportive relationships are critical for achieving and sustaining resilient adaptation. During the childhood years, early relationships with primary caregivers affect several emerging psychological attributes and influence the negotiation of major developmental tasks; resolution of these tasks, in turn, affects the likelihood of success at future tasks. Accordingly, serious disruptions in the early re-

lationships with caregivers—in the form of physical, sexual, or emotional abuse—strongly impair the chances of resilient adaptation later in life. Whereas some maltreated children will obviously do better in life than others, the likelihood of sustained competence, without corrective, ameliorative relationship experiences, remains compromised at best. On the positive side, strong relationships with those in one’s proximal circle serve vital protective processes, for children as well as adults.

Two broad ingredients are well known to be important in good relationships: warmth and support, and appropriate control or discipline. These dimensions have been at the core of childhood socialization research for decades. Moreover, recent research shows that later in life, strong intimate relationships, such as those in marriage, provide both the support and the informal social control needed to negotiate ongoing challenges in life.

There are several aspects of protective family processes that warrant further attention in future research, such as dimensions of containment and investment (children’s beliefs that parents will prevail in disciplining them and protecting them from harm, respectively) and the role of consistency in simple family routines such as regularly eating dinner together. Also needed is much more work on parenting as a dependent variable. Good parenting is beneficial to all children and, to this extent, is ordinary (Masten, 2001). On the other hand, it is clearly extraordinary among at-risk families because it is so difficult to sustain in the face of major life risks such as chronic poverty and major mental illnesses. A central task for the future, therefore, is to identify the specific protective processes that make for positive parenting patterns among parents in high-risk circumstances, as well as the processes via which intervention programs eventuate in improved parenting behaviors.

Additionally, more needs to be learned about the specific relationship ingredients that are particularly influential or important in the context of particular types of risk; in neighborhoods rife with community violence, for instance, strategies to ensure physical safety are clearly of unique importance. Similarly, there must be more research on developmental processes in ethnic minority families. These individuals experience several stressors, including overrepresentation in poverty and experiences of discrimination, and there should be greater inquiry into factors that (in addition to the universals, such as warmth and discipline) are especially salient in particular ethnic minority groups. Examples of such factors include notions of family responsibility, support, and obligations both in the immediate and the extended family, as well as racial socialization and ethnic pride.

Aside from these dimensions of psychological processes, a critical priority must be to explore the role of genes in relation to familial influences on resilience. We know that both genes and the environment affect outcomes, and resilience researchers must increase their attention to the former. Studies are needed that illuminate gene \times environment interactions in resilient adaptation and genetic markers conferring vulnerability or resilience, with attention to the mechanisms that might underlie their effects.

In the community domain, a major message from extant research is that ongoing exposure to community violence is highly inimical not only for children but also for their parents and other adults. Among those who fear for their very lives, it is unrealistic to expect psychological robustness: When physical survival threatens, all developmental tasks and processes are jeopardized. In the case of such risks, therefore, our first order of business should be to focus on eradicating these experiences in whatever way possible. This is not to say that we should cease attempts to attend to factors allowing some exposed individuals to fare better than others. Rather, the suggestion is that even as we attempt to identify such protective processes, any reports of research findings must be accompanied by unequivocal statements that these experiences are highly noxious and fundamentally undermine children's abilities to do well over time. In the interest of averting research-based impressions that some do indeed rise above such potent risks, we must caution, as we present our findings, that all regularly traumatized children are damaged in some integral way.

The community can be an important source of alternative support and care when the child's own parents are unable to provide these. High-quality child care is particularly helpful for children in the most at-risk families, as strong, supportive relationships with teachers can be highly beneficial for school-age children and adolescents. There is also great potential to use K-12 schools as a venue to foster resilient adaptation. Thus far, several school-based interventions based in social control and social learning theories, involving teachers as well as parents, have shown some success in randomized trials. What remains insufficiently explored is the effectiveness of attachment-based interventions in schools, where the emphasis is on developing close, supportive bonds with teachers that are sustained for as long as is feasible. Paralleling future work with parents, scientists need to learn more about resilience-inducing teachers by illuminating the factors that enable some teachers to bring out the best in their at-risk students. In addition, interventions using positive peer relationships to foster resilience warrant further exploration. In considering the enhanced use of schools to foster re-

silience, it will be critical to (1) disseminate evidence that psychological problems impair achievement, (2) carefully consider contextual factors (characteristics of the school and the wider community), and (3) maximize use of existing resources rather than necessarily seeking new ones.

Support provided by informal mentors (as in Big Brothers Big Sisters) can also serve important protective functions, especially when the relationships are of relatively long duration. Similarly, involvement in religion, can confer benefits via the availability of a stable support network in addition to promoting relatively positive coping strategies. At the neighborhood level, cohesion and shared supervision of children are important positive influences, as is high participation in local and voluntary organizations. Children benefit from participation in structured extracurricular activities, but unstructured settings (as in youth recreation centers) can exacerbate risks. In the years ahead, it will be useful to explore more interventions that involve families in the context of their communities, with emphasis, on developing strong networks among parents, school personnel, and neighborhood groups and agencies.

People's personal characteristics obviously affect resilience, but many personal attributes are themselves shaped by aspects of the external environment, especially among children. This is powerfully demonstrated in evidence on changes in cognitive ability as a function of the quality of the early environment in orphanages versus adoptive families. Other protective traits, such as good self-regulation, high self-efficacy, and internal locus of control, are also highly affected by the quality of proximal interpersonal relationships.

Studies with adults have suggested the importance of several personal attributes relatively rarely examined thus far in the context of childhood resilience, including practical and emotional intelligence and the capacities for insight, empathy, and altruism. The ramifications of developmental maturity are complex: Whereas developmentally mature defense mechanisms are often beneficial, there can be times when repressive coping can be helpful (e.g., among bereaved adults). Similarly, high ego developmental level is generally an asset but can be linked with heightened tendencies to self-recrimination and rumination. In future research, there is value in studies not only on the changing developmental significance of these various psychological attributes, but also on the functional capacities that might lie at their roots.

As with family factors, of critical importance in the realm of personal characteristics are more studies on biological attributes, with attention to dimensions outlined in the first section of this paper: hemispheric EEG activity,

the startle reflex, stress hormones, and neurotransmitters such as serotonin. Just as the environment sets confidence limits within which biology determines functioning, biology sets limits within which the environment determines adaptation levels. If there is a chemical imbalance in the brain that predisposes a person to depression, then the threshold of tolerance to environmental stressors becomes considerably lower, so that even stressors of moderate severity could precipitate a debilitating depression. In many instances, discovery of the biology involved in psychiatric disorders can pave the way for appropriate pharmacological interventions.

Research Designs: Optimizing Selection of Risk Modifiers for Study

Aside from these suggestions about specific research questions and topics, there are some broader guidelines that are critical from an applied research perspective, and these have to do with prioritizing domains targeted for inquiry. The evidence presented in this chapter reflects enormous progress in the field but at the same time has the potential to be somewhat overwhelming. Knowing that resilience is affected by multiple processes at the social, psychological, and biological levels, often interlinked bidirectionally, how does the resilience researcher best design future research? How should one prioritize in terms of the types of constructs and questions most usefully examined in the years ahead?

A major consideration in designing research that will truly move this field forward will be to ensure *concerted attention to context* in selecting risk modifiers for empirical study. We know that there are certainly some processes that are beneficial across contexts and others that are harmful. Beyond such universals (such as closeness and discipline in families), there are risk modifiers that can be highly influential in some risk settings but not others, and we need more within-group studies that consider these processes simultaneously, disentangling their relative significance in particular contexts. Exemplifying this are the following two illustrative questions. Beyond warmth and discipline, among children of depressed parents, what is the relative significance of the following as protective family attributes: support from the nondepressed parent, open discussions on the causes of depression, maintenance of regular family schedules, and low genetic loading for affective disorders in the other parent? Among children in highly affluent, achievement-oriented communities (and again, beyond warmth and discipline), what is the relative influence of the amount of down time spent as a family, a

large number of weekly extracurricular activities for children, and parents' high standards for performance and their tendency to be overtly critical of children's failures?

A useful rule of thumb, particularly for scientists with a largely applied focus, will be to focus most intensively on risk modifiers with high *promotive potential*, as defined by five major characteristics: forces that are:

1. Conceptually highly *salient* in the context of that particular high-risk setting;
2. Relatively *malleable*, or responsive to environmental interventions;
3. *proximal* to the individual rather than distal;
4. *enduring* for long periods in the individual's life; and
5. *generative* of other assets, catalyzing or setting into motion other strengths and mitigating vulnerabilities.

Early family relationships meet all of these five criteria, being salient across risk settings, modifiable via interventions, directly affecting the child, exerting this effect for several years, and catalyzing other assets such as high self-esteem and positive views of relationships. Another example is the receipt of high-quality early childhood education. This is particularly important in low-income communities, can be provided by external interventions, directly affects the child and over several years, and, again, produces functional capacities that, in turn, promote the acquisition of diverse cognitive as well as psychological and social skills.

Of parallel importance would be reduction of influences with high *vulnerability potential*, those that are contextually salient, modifiable via interventions, proximal, relatively enduring in the absence of interventions, and generative of other vulnerabilities. An example is youth's involvement in deviant peer networks. Biological vulnerabilities also could fall in this category, as deficits in serotonin can be salient among individuals in families with high genetic loading for depression; these deficits can be modified pharmacologically; they directly affect the individual's everyday functioning; they tend to be stable in the absence of interventions; and in inducing depressive affect, they lead to other problems that further compromise adjustment, such as loss of relationships or jobs.

In conclusion, the field of resilience has grown enormously, and in exciting ways, in the half-century or so since its inception. At this stage, scientists must broaden the lens through which the phenomenon is viewed, drawing on not only quantitative developmental psychology research but also biological, genetic, anthropological, sociological,

and clinical evidence. It would also be beneficial to move beyond conceptualizing the search for processes simply in terms of the triad of family, community, and individual factors. To best inform future interventions, researchers must consider the resilience-enhancing quotients of the specific risk modifiers chosen for study—in terms of their contextual salience, malleability, proximity, stability, and generativity of other processes—as well as the degree to which the constructs and questions might illuminate our understanding of psychological, biological, and social processes implicated in resilience. Concerted efforts in these new directions are critical if we are, in fact, to borrow from Curtis and Cicchetti (2003, p. 773), to “move research on resilience into the twenty-first century.”

SUCCESSFUL AGING: A THEORETICAL FRAMEWORK	827
A Theoretical Framework for Research on Resilience in Middle and Late Adulthood	827
RESILIENCE IN LATER ADULTHOOD AND OLD AGE: PERSPECTIVES FOR RESEARCH AND INTERVENTION	829
REFERENCES	832

From its very beginning, human development is dependent on the physical and social context for support. Some of this support is very basic and is required equally by all people (air, water, food); other support is more complex (social care, language training) and is necessary to varying degrees (culture-specific competencies, multilingualism). Individual demand profiles vary widely: People may have hereditary and acquired vulnerabilities or deficits that require support and

fostering, including specific kinds of intervention and preventive measures (e.g., special diets in the case of inherited metabolic disorders such as phenylketonuria). But in all cases, development can take place only given an appropriate fit between individual and environment. Within the range of possibilities that meet this requirement, human development can unfold in a wide variety of ways. Even if all the necessary preconditions have been fulfilled, development, if it occurs at all, by no means follows a predetermined path. The dispositions and characteristics inherent in each individual and in human beings in general are confronted by an incalculably vast array of environmental influences (education and socialization, learning environments and experiences, biographical characteristics and influences, critical and nonnormative life events, historical influences, etc.). These factors, furthermore, extend their influence throughout the entire process of ontogenesis (P. B. Baltes, 1987; P. B. Baltes, Lindenberger, & Staudinger, 1998).

A large body of empirical and theoretical research, however, supports the idea that negative changes increase in

This text is in many ways a follow-up to the chapter "Resilience and Reserve Capacity in Later Adulthood: Potentials and Limits of Development across the Life Span" (Staudinger et al., 1995), which appeared in the first edition of this book. The present chapter expands on the considerations and theories presented there, offering modifications of some details but taking fundamentally the same approach. Therefore, we do not mention each of the parallels and shared lines of argumentation in an explicit citation. One of the authors of this chapter, Werner Greve, would like to thank the colleagues who authored the earlier chapter for their many useful comments and suggestions.

later adulthood and old age, as everyday experiences and stereotypes might indeed lead us to expect (P. B. Baltes, 1997). At the same time, many studies show that for the large majority of older people, subjective well-being does not decrease in later adulthood (Brandtstädter, Wentura, & Greve, 1993; Staudinger, 2000b), at least into the early phases of old age (P. B. Baltes, 1997). This implies the existence of different mechanisms at work, which buffer or completely absorb the impact of increasingly negative development influences.

This aspect of aging has never been more important than it is today, at the beginning of the twenty-first century: Society is graying (Williamson, 2002), and historically speaking, this is a “young” phenomenon (P. B. Baltes & Baltes, 1990). Nevertheless, despite the growing population of elderly people—both because more people are living to reach old age and because on average they are living longer (Maier & Vaupel, 2003)—there is much evidence that elderly people in *this* aging society will do better socially, physically, and psychologically than any older generation before them. In the last decade of the twentieth century, for example, extensive evidence was published indicating that older people do not develop symptoms of clinical depression more frequently, but in fact less frequently than younger people. Furthermore, they often remain fully capable of social interactions after cognitive deficiencies arise (for a summary, see Carstensen & Charles, 2003). Although these findings contradict many of our expectations (which are probably derived in part from textbooks on developmental psychology and gerontology), they may be more than just the exception to the rule. Kegan (1998, p. 198) reports what a friend told him when she reached her 50th birthday: She experienced none of the symptoms of “empty nest syndrome” (which she had expected), but realized that “the true meaning of liberation is when the last child goes off to college and the dog dies.” This does not challenge the idea that aging is associated with losses, but suggests that these losses can be compensated for in manifold ways. Furthermore, it emphasizes that consequences of these losses are less severe than widely feared and that their onset occurs at an increasingly later stage in the life course.

Aside from the fact that this is good news to most of us, *why* is it the case? An initial answer is: because of the progress in medicine and in social and medical care—in short, the high living standards that prevail in the Western world. But we argue that this answer falls short. Above all, providing for people’s physical and material needs is not everything. Even when these needs are met, age-correlated losses frequently still occur, for example, the end of work-

ing life, children leaving home, the deaths of loved ones, or diminishing fluid cognitive competence (mechanics). Why does the “paradox of well-being” (Staudinger, 2000b) still prevail? Why do the majority of older and elderly people not get sick or show any significant decline in their well-being or mental health? To help answer these questions, this chapter seeks to better understand and explain the phenomenon of *resilience*.

The importance of resilient adaptation in the face of adversity, in particular in childhood and adolescence, has been stressed in several papers and books (e.g., Cicchetti, Rappaport, Sandler, & Weissberg, 2000; Glantz & Johnson, 1999). Only recently has this concept been expanded and applied to later stages of life, in particular to late adulthood and old age (Brandtstädter, 1999b; Staudinger, Marsiske, & Baltes, 1993, 1995). In the present chapter, we argue that resilience—beyond childhood and adolescence, but also beyond old age—is a central concept for both the life span perspective on human development and for developmental psychopathology. It conveys the idea that individuals can avoid negative outcomes or decreasing trajectories of development despite the presence of significant risk factors in their environment or potentially harmful experiences during their lives. It also includes the proposition that individuals can return to a normal, or their initial, level of functioning following developmental setbacks or crises, either with or without external support (e.g., Garmezy, 1991; Masten & Coatsworth, 1998; Rutter, 1987). By explaining the processes and mechanisms that stabilize, protect, or help in the recovery of the psychological functions affected in each particular case, it will not only become more evident how development actually works, but also that negative developments and maladaptation cannot only be explained by the *presence* of specific risk factors, but also by the *absence* of protective factors. Obviously, this implies that risk and protective factors are defined independently.

As mentioned, both scientific conceptions and widespread stereotypes traditionally associate age and aging with loss, decline, and negative changes. In the following, we argue that such negative stereotypes and conceptions of aging are in part wrong, but for most one-sided (despite their usefulness for stabilizing processes in downward comparisons, e.g., Heckhausen, 1999; Pinquart, 2002; Rothermund, 2005). We pursue the thesis that the majority of aging individuals are able to maintain a satisfying level of functioning and social networks and to stabilize their subjective well-being, life satisfaction, and sense of identity and self-esteem. We argue that this ability to preserve the quality of life throughout long phases of middle and

late adulthood and into early phases of old age is both an expression and a result of resilience-related processes and resources. This claim has two implications. First, resilience is not the exception but the rule: Resilience is a much more common and ordinary phenomenon than was thought in early stages of investigation (Masten, 2001). Second, it follows from this that processes of resilience substantially contribute to the explanation of development in later adulthood and old age in general. Thus, the perspective on resilience presented in this chapter also contributes to our understanding of what adult development and aging actually is.

In this chapter, resilience in later adulthood and old age is investigated from the perspective of life span development. According to this view, human development is characterized by multidirectionality, multifunctionality, plasticity, and permanent change of the individual's experiences of gains and losses (P. B. Baltes, 1997; P. B. Baltes, Lindenberger, et al., 1998; P. B. Baltes, Staudinger, & Lindenberger, 1999; Staudinger & Lindenberger, 2003a). Human development is embedded in historical, cultural, and social contexts. Thus, an individual's course of life cannot be understood or explained without referring to the historical circumstances, the cultural influences, and the social interactions that frame and form it. Although age-graded and nonnormative individual experiences and events determine the individual's development throughout the life span, development is necessarily *development in context*. Socializing agents (parents, peers, partners, and teachers) actively influence and shape our biographies, and their efforts and actions depend to a large degree on the cultural framework within which they act.

Moreover, human development is, to a large degree, actively and intentionally steered and regulated by the developing individual (Brandtstädter, 1998; Brandtstädter & Lerner, 1999). To some extent, we are and become who and what we want to be (Greve, Rothermund, & Wentura, 2005). Yet, the implied intentionality contained in this phrase, even if it is accepted, carries a variety of connotations. Some approaches argue that humans intentionally coproduce their development (Brandtstädter, 1998; Brandtstädter & Lerner, 1999; Greve, 2005; Lerner, Dowling, & Roth, 2003); others take a constructivist stance and interpret "producing" as semantic reconstruction (Straub, Zielke, & Werbik, 2005). Within this range of perspectives, one central aspect of resilience includes the adaptive processes and the dynamic interplay between the pursuit of personal (developmental) goals and the (developmental) adjustment of these goals to constraints, losses, or changes

in action and developmental resources (Ryff, Singer, Love, & Essex, 1998; Staudinger et al., 1995).

Hence, resilience is one of the key features of psychological aging. We are interested here not only in studying the "normal" occurrence of resilience, but also in showing how it can be fostered and enhanced both by the social environment and by intentional intervention. In research on resilience during childhood and adolescence, modes of supporting resilience have long been recognized (Cicchetti, 1993; Masten, 2001; Masten & Coatsworth, 1998; Werner, 1995). With respect to late adulthood and old age, however, options and opportunities for actively supporting resilience have only recently gained attention (with the exception of cognitive training; Ryff et al., 1998; Staudinger et al., 1993, 1995). The activation of resilience constitutes a central interface between life span development and developmental psychopathology, two domains that we aim to connect more closely in this chapter.

A LIFE SPAN PERSPECTIVE ON DEVELOPMENT IN LATER ADULTHOOD AND OLD AGE

Resilience, as we conceptualize it in this chapter, entails plasticity (cf. Staudinger et al., 1995). Plasticity, in turn, is a central concept of the life span approach to development. Thus, we start our discussion by presenting an overview of the central assumptions and concepts of life span psychology.

The life span approach to human development is characterized by six central propositions (e.g., P. B. Baltes, 1987): (1) Human development actually continues throughout the whole life span, (2) it proceeds multidirectionally, (3) it can be described as a gain:loss ratio, (4) it reveals great plasticity, (5) it is comprehensible only with reference to its historical embeddedness, and (6) a scientific explanation of development has to include contextualism as a paradigm (see also P. B. Baltes, 1987; P. B. Baltes, Reese, & Lipsitt, 1980; Lerner, 1984).

At the beginning of this debate, developmental psychologists extended their perspective beyond youth and adolescence to also include later phases of life, focusing their investigations mainly on late adulthood and old age. In these early days, the life span perspective on human development was sometimes difficult to distinguish from gerontopsychology. However, more recent approaches (e.g., P. B. Baltes, 1997; P. B. Baltes, Lindenberger, et al., 1998; Brandtstädter, 1998; Roberts & Caspi, 2003; Staudinger & Bluck, 2001; Staudinger et al., 1995) are finally linking with earlier longitudinal studies on childhood and adoles-

cence that have “grown older” over the years (e.g., Eichorn, Clausen, Hann, Honzik, & Mussen, 1981; Hetherington, Lerner, & Perlmutter, 1988; Pulkinen & Kokko, 2000; Reese, 1993; Sorensen, Weinert, & Sherrod, 1986). This link is carried by the idea that the life span perspective on human development offers a unique and integrative perspective on development that goes far beyond the simplistic claim that developmental changes can be observed in every stage of life. This approach is incompatible with reducing development to stages or with portraying the second half of life as largely a period of decline and despair. Understanding development throughout the life span as multidirectional (i.e., encompassing gains and losses at the same time) and modifiable implies a view on aging that acknowledges the losses but also focuses on stability and gain. Thus, this view challenges models of aging that are oriented *exclusively* toward decrements (P. B. Baltes, 1993; Riley & Riley, 1989; Rowe & Kahn, 1987). Rather, it conceptualizes development over the individual’s entire lifetime as a dynamic ratio of gains and losses. This applies not only to later life, but also to childhood, a period that is often viewed as characterized exclusively by progression and increase. As early as 1965, Piaget described some visual illusions that increase with age and others that decrease. Even on a neurological level of description, when looking at brain development between the ages of 8 and 12 months, we can observe the phenomenon of neural pruning, that is, the disappearance of neural connections that were established in earlier flourishing phases but are no longer useful or necessary (e.g., Huttenlocher, 2002). At the same time, there are domains of cognitive functioning that show stability through old age. For instance, work on wisdom has repeatedly demonstrated the considerable progression and advantages of older adults with respect to life experience and advice (e.g., P. B. Baltes & Staudinger, 1993, 2000; Staudinger, 1999a; Staudinger & Baltes, 1996). Even in the development of memory, an area prototypically connected with decline in old age, there is evidence that implicit memory shows stability or even increases across the life span (Graf, 1990; Howard, 1991). Moreover, what constitutes a developmental gain or loss is a complex question and changes with age, both subjectively and theoretically (we return to this issue later).

These propositions delineate a research program that aims to identify the processes and potential of individual development—within the specific cultural and historical context (the present chapter aims to contribute to this). Please note, however, that the propositions of the life span perspective on human development (P. B. Baltes, 1987) refer to different conceptual levels. They lend themselves

more or less directly to empirical testing. The proposition that human development is a lifelong process is not so much a directly testable hypothesis as it is a conceptual perspective that does not equate development with increase or gain. Even in the first half of the twentieth century, the debate was not about whether or not in part severe changes occurred during old age, but about whether they should be conceptualized as *development*. The life span approach (and this chapter as well) proceeds from the understanding that development at all ages (including old age) is a ratio of gains and losses. Similarly, the commitment to contextualism as a research paradigm is foremost a methodological demand and, as such, not empirically falsifiable; it highlights the crucial forms of interaction that are missed by focusing on the individual. This is also true of the demand that historical embeddedness be taken into account. Although this proposition reflects primarily a methodological and theoretical requirement, the ignorance of cultural and historical contexts would certainly lead to false inferences about development.

The theory of the plasticity of organisms or their attributes, and thus of their development (Lerner, 1984), poses a number of empirical challenges. In this context, it is crucial to underscore that the two concepts of development and plasticity in principle are not logically interdependent (they are, of course, interdependent in a life span perspective of development). Basically, the claim of plasticity of organisms and their courses of development would also be compatible with a concept of development that is limited to specific phases of an organism’s evolving complexity. In this respect, there are indications that in the first few months of life, brain structures pass through sensitive developmental phases that are almost impossible to be compensated later. Simultaneously, it was demonstrated that the brain remains plastic even into advanced old age (Li, 2003). When the idea of plasticity and thus the context sensitivity of development is taken seriously, a narrow concept of development as a sequence of qualitatively separable stages of development that ends when “maturity” is reached in adolescence appears highly implausible. However, claiming development as a gain:loss ratio (Smith, 2003) makes it crucial to demonstrate significant gains and losses across the whole life span (a few examples have already been cited).

How do gains and losses come about? Life span psychology claims that gains and losses do not simply follow an age-graded biological program. Rather, we need to take into account age-graded cultural influences such as norms that regulate behavior at different phases in our life (Heckhausen, 1999; Kim & Moen, 2001a, 2001b;

Neugarten, Moore, & Lowe, 1965). Those norms not only operate as a constraint for the age-related behavior in question, but also determine the self-image of the aging person and thus influence which competencies are used or trained and thus maintained over time (e.g., individuals who do not walk or jog on a regular basis can be expected to experience a tendency toward reduced mobility). Besides, biology and culture, the two big sources of development, themselves change depending on historical time. Due to medical and nutritional progress, we seemingly have become biologically “younger” at higher ages. And clearly, historical influences, such as a war, change development across ages. Finally, we need not forget the importance of idiosyncratic constellations and events on development.

Development as Lifelong Transactional Adaptation

The central claim of the life span development approach is, obviously, that developmental changes occur from birth until death. The developmental processes that occur throughout the life span are not simply the mechanical unfolding of predetermined maturational programs, or the cumulative expression of the reactions of the developing organism to environmental conditions or stimuli. Rather, development can be characterized as “transactional adaptation” (e.g., Lerner, 1984, 1986) or continuous “person-environment interaction” (e.g., Magnusson, 1990). In short, development is adaptation. Human development in context can be viewed as a system of structures that must integrate through a transactional process of adaptation (Ford & Lerner, 1992; Lerner et al., 2003; Masten & Coatsworth, 1995; Thelen & Smith, 1998). The phenotypic appearance of development is the present outcome of the individual’s interactions with changing contextual circumstances (influences, stimuli, stable conditions) under the prevailing genotypic and sociohistorical constraints or facilitators. Moreover, some of these circumstances and conditions are not only actively selected by the individual, but also actively shaped and modified (Caspi, 1998; Roberts & Caspi, 2003; Scarr & McCartney, 1983). This person-environment interaction is thus not a one-way street, but a real *transaction*, in which both person and environment experience (developmental) changes. Individuals transform their contexts and are transformed by their contexts, sometimes simultaneously. As a consequence, the investigation of (human) development has to take into account several levels of observation, and hence levels of explanation. Not only psychological functions change with age, but so do contexts, and the risks, resources, and functional consequences asso-

ciated with them. To give one example, our speech competence (vocabulary, fluency, etc.) develops with age, but so do the contexts and conditions in which language changes are acquired and used. One major consequence of an interactional perspective on human development is that the environment becomes pivotally important for a proper understanding of developmental processes. Far beyond being a mere cue or motor for these processes, context has to be viewed as a constitutive part of it. Accordingly, Ford and Lerner (1992), following several earlier propositions (e.g., Oyama, 1985), talk about “developmental systems” (see also Lerner et al., 2003).

Continuity and Discontinuity

Developmental processes may appear continuous or discontinuous. For instance, in both the intellectual domain and the personality domain, different authors have reported mean level and interindividual retest stability on repeated occasions (Costa & McCrae, 1988; Hertzog & Schaie, 1988; Schaie, 1994; Siegler, George, & Okun, 1979), indicating a high level of individual stability for each respective aspect. At the same time, however, Nesselroade (1991) has argued empirically and theoretically that there are several indicators of remarkable intraindividual variability. Thus, individual continuity and group-level stability have to be reconciled with individual variability. As will become increasingly clear in later sections, it is one of the theoretical aims of this chapter to demonstrate that the concept of resilience can be understood as the crucial theoretical link between continuity and change.

However, development can also be characterized by phenotypic discontinuity, that is, by disruption or innovation. Innovation is perhaps the classic constitutive concept of development. From Piaget to Erikson and Havighurst, when the individual is confronted with a new challenge, “crisis,” or “developmental task” (Erikson, Erikson, & Kivnick, 1986; Havighurst, 1973; Labouvie-Vief, 1982; Levinson, 1978; Oerter, 1986) that disturbs its “equilibrium,” he or she has to assimilate the disturbing information or accommodate the disturbed part of the system. By doing so, the individual develops toward a new level (often characterized as a higher level) of intellectual or personal functioning. It is the crisis that promotes development. For instance, the transfer from school to an employment context in late adolescence presents the individual with an array of new tasks and challenges, as well as opportunities that have to be dealt with, that require adaptation of concepts and competencies, and that, in short, force development. Retirement or children leaving home are further examples of life changes with developmental consequences.

In this context, the term “continuity” bears potential for misunderstanding. Besides connoting constancy and stability (as opposed to change), it can also signify *continuous change*. For example, the decrease of mobility and sensory functions in later adulthood (P. B. Baltes, Lindenberger, et al., 1998; Lindenberger & Baltes, 1994) occurs, under normal conditions at least, not suddenly, from one moment to the next, but as a *continuous* process. As such, it requires—and at the same time facilitates—*permanent* adaptation of the developmental system (i.e., the organism itself, the internal self-representation, physical and social support systems). Thus, continuity can also be interpreted as a process of change without reversals or gaps. Because this is probably the most typical form of developmental process (we usually do not even recognize that we are “currently developing”), continuity can in a certain sense be considered an essential part of development, even if the concept of development should entail qualitative changes. As will become clearer in later sections, this is one of the reasons resilience is not a phenomenon separate from development, but is itself a developmental concept.

Finally, continuity, stability, and change depend on the level of observation. Whereas a certain process can be viewed as continuous from one perspective, it can appear as changing from another (Brandtstädter & Greve, 1994b; Lerner, 1984). For instance, although a tightrope walker’s progress along the high wire appears to be completely continuous (stable), at the level of neuronal and muscular phenomena almost everything is in motion (unstable). In short, development as a phenomenon does not depend on the immediate visibility of dramatic changes. Rather, phenotypic stability (say, of personality) can be, and often is, precisely the result of developmental processes that enable and maintain this stable aspect of the person (P. B. Baltes, Staudinger, & Lindenberger, 1999; Greve, 2005). In turn, phenotypic continuity and stability as well as discontinuities can result from interactive processes that combine—that is, integrate—both stable and variable components. Thus, one central tenet of the life span developmental perspective is that we can never infer stable causes from stable outcomes or variable causes from observable changes.

Multidirectionality and Multidimensionality of Life Span Development

If lifelong development always entails gains and losses, then every conception that claims that development is confined to gains and to one universal goal, that is, a higher state of functioning, is rendered untenable. Numerous concepts from developmental psychology do, however, contain precisely this implication, such as the concept of

“maturing out” (Vaillant, 1993). One consequence of the life span approach is that such concepts can be applied only to specifically defined domains, for example, to the maturation of specific organs or the development of basic competencies (e.g., walking, digestive control, sexual maturation). When various domains of functioning are considered together, however, one must assume that development is multidirectional at one point in time, which is obviously true within individual domains of functioning as well. Thus, the differentiation between fluid and crystallized intelligence (P.B. Baltes, Staudinger, & Lindenberger, 1999) shows that in the domain of cognitive abilities, different developmental trajectories exist for different aspects. Similar differentiations have been suggested for the area of personality development (Cloninger, 2003; Staudinger & Pasupathi, 2000).

The concept of multidirectionality is inextricably linked to conceiving development as multidimensional. Not only does a one-sided focus on individual domains of functioning (e.g., intellectual capacities) ignore the multifacetedness and heterogeneity of developmental processes, it also causes salient interactions between different domains of functioning to be missed entirely. The close interaction between cognition and sensory functioning or between cognition and motor performance are two illustrations of this. Development is based on three major influences: biology, culture, and the developing individual. These three forces vary in their importance between domains of functioning and depending on chronological age. For instance, the pragmatic component of cognitive functioning is more strongly based on cultural than on biological influences, whereas for the mechanic component, the opposite is the case (e.g., P. B. Baltes, 1987). Only through this multidimensionality can multidirectionality, as discussed previously, ultimately be understood. Thus, during adolescence, for example, an increase in some abilities (e.g., physical strength, sexual maturing) is accompanied by a decrease in others (e.g., ease of language acquisition)—a further example of the permanently fluid gain:loss ratio.

Numerous findings do, however, favor the idea that this individual gain:loss ratio worsens steadily over the life course; as we age, we register this as well (Heckhausen, Dixon, & Baltes, 1989). One should not jump to hasty conclusions here, however: Individuals register their particular losses in a *domain-specific* manner. If we add up all of these individually registered losses (see Brandtstädter et al., 1993), we see that with increasing age, the losses outweigh the gains—objectively, as it were. But in assessing these losses, the individual weights them individually (and metaphorically speaking, the weight of some losses

may even be 0), such that the *individual* balance may differ significantly from the objective balance. In addition, individuals tend not to assess all domains in a balanced manner. Instead, as a rule, we focus on one specific domain (which explains why one's current self-image within the "working self" can vary so widely from situation to situation; Hannover & Kühnen, 2005). It all depends, in other words, on one's internal, subjective evaluation and perspective. We return to this in greater detail later, as this aspect already hints at a process that is central to resilience (with regard to specific domains). For the purposes of our argument at this stage, however, it is important to note that the respective domain-specific losses are not in general denied or refuted: Defensive coping strategies (e.g., Haan, 1977; Vaillant, 1993) may sometimes be useful for practical purposes (e.g., Lazarus & Golden, 1981) but are not the major force underlying resilience.

Inter- and Intraindividual Variability of Life Span Development

This leads to a further point of pivotal importance for the study of resilience at an advanced age from the life span perspective. Human beings differ among themselves, in some cases considerably, and not just at particular points in time but also with regard to entire developmental trajectories. There are significant interindividual differences in the magnitude, timing, sequencing, and even directionality of change throughout the life span. Interindividual differences tend to increase as we age. Whereas some people are able to preserve their intellectual acuity and mental abilities up to an extremely advanced age, others already begin to show decreased mental faculties at a very early age. Even if one can generalize that negative changes are to be expected and are therefore normal in some cognitive domains (memory, speed of information processing, concentration) in the 7th and 8th decades of life (Salthouse, 1991), some people experience these changes earlier than others, and others experience them to a lesser degree or not at all (Nelson & Dannefer, 1992; Schaie, 1996).

In addition, there is a significant level of *intraindividual variability* in these changes *between* different domains (Nesselroade, 1989). The domain- and age-specific intraindividual variability of development is important as it demonstrates the plasticity of development, a central precondition for resilience to occur. An individual's intellectual performance on an achievement test can vary dramatically depending on the prevailing personal and situational conditions (e.g., distraction, fear, fatigue, preparation, practice, disturbances). Furthermore, this domain-specific intraindividual variability helps to prevent stark generalizations from becoming established stereotypes. It is not necessarily given

that a person experiencing deterioration processes in one functional domain will also show functional losses in all others as well. A person who is physically frail, for example, can still remain intellectually alert, creative, and productive (e.g., Smith & Baltes, 1993).

In summary, the concepts of multidimensionality, multidirectionality, and, in particular, interindividual and intraindividual variability indicate that an almost infinite variety of developmental constellations can emerge. The degree of phenotypically recognizable individuality tends to increase over the life course (at least up to age 85), first because the individualizing (nonnormative) influences of the biography cumulatively increase, and second because the canalizing effect of preformed biological dispositions decreases (P. B. Baltes, 1993, 1997; Staudinger & Lindenberger, 2003b).

Development as Dynamic Change of Individual- and Domain-Specific Gain:Loss Ratios

What may be the central hypothesis of the life span perspective on human development is that the numerous changes people experience in the course of their lives do not have any a priori fixed directionality. Even in particular domains or phases of development that appear very uniform (e.g., learning to walk in the first 12 months of life), there is actually a high degree of individual variability: Strongly divergent trajectories can always emerge (e.g., with hereditary physical disabilities), and changes beyond midlife show that physical mobility does not demonstrate generally "upward" development over the entire life span. Each area can show gains, stability, or losses in each phase of development, both objectively and subjectively. From the perspective of the approach taken here, development consists of a highly interlinked system of changes in different directions that can have different consequences—either positive or negative—from case to case (P. B. Baltes, 1987, 1997; Staudinger & Lindenberger, 2003a; Weinert, 1994). As will become clear in this chapter, although processes of resilience ensure in many ways that the individual achieves a tolerable or even satisfactory final result overall, these diverse mechanisms naturally also contain the potential for maladaptive and dysfunctional processes. Developmental psychopathology thus seeks to identify the risk factors and developmental constellations that render individuals vulnerable and can lead to pathological development trajectories (Cicchetti, 1993; Cicchetti & Garmezy, 1993; Jessor, 1993; Rutter, 1987). This is precisely the point where developmental psychopathology and life span developmental psychology meet.

The perspective discussed here—that development should be conceptualized as a dynamic system of gain:loss

ratios (Smith, 2003)—goes far beyond merely establishing the existence of multidirectionality within and between different domains of development. It aspires to the idea that the processes of human development can be understood only when the organism and the environment with which it interacts are understood as a complex developmental system (e.g., Ford & Lerner, 1992; Lerner et al., 2003). The different developmental domains discussed earlier interact with the environmental resources that are affected or involved in each particular case, and this creates the dynamic system of gains and losses. In addition, the individual's resources (energy, time, material resources, etc.) are always limited (P. B. Baltes & Baltes, 1990; Staudinger et al., 1995), and thus each investment decision for a task in one domain at least implies opportunity costs that usually also result in losses in other domains (e.g., Brandtstädter & Wentura, 1995; for an economic perspective on human development, see Berman, 2003). As it is not possible to do everything, it is necessary to make choices that will in turn result in other decisions and thus canalize development (cf. Edelman, 1987; Waddington, 1975) and possibly have ripple effects far beyond the development domain originally considered. Thus, even these kinds of investments, which bring about gains (e.g., practicing the piano, which leads to an improvement of playing skills and possibly increased overall musicality and pleasure from music), also imply losses (during the same period of time, one has played less sports, cultivated fewer social contacts, read or danced less). In the extreme case, this can lead to a one-sided and premature draining of resources: Someone who “gives everything” to reach a goal pays a high price in the end, even if the goal is ultimately achieved (e.g., the father who neglects his wife and children, not to mention his own health, to meet his career objectives), and may realize too late that the goal was not worth the price. If this individual does not achieve the goals for which he has made so many sacrifices, he or she may lose everything. Furthermore, many resources diminish with age (Baltes, 1997; Staudinger et al., 1995): physical resources in particular, as we will see later, but social resources as well. This process increases the probability of risk constellations and in turn alters the conditions for resilience and recovery under threatening and burdening circumstances.

Influences on Individual Development: The Interaction between Biological Disposition, Sociocultural Context, and Volitional Action

Developmental contextualism (Lerner & Kauffman, 1985; Reese & Overton, 1970; Riegel, 1976) and other approaches share the central assumption that development is

always the product of a complex interaction between nature and nurture, genes and environment, individual and social influences. The evaluation of a given behavior or behavioral change has always to refer to a certain context; this is true particularly when categorizing a given behavior or pattern of adaptation as psychopathological (Cicchetti & Aber, 1998). A certain attribute or competence may be considered helpful and adaptive in one environment or situation, but maladaptive or a burden in another. For instance, the goal to overcome obstacles and to stick tenaciously to one's purposes may help in finally reaching one's goals in situations that do not exceed one's resources (e.g., in a complicated professional task), but the very same goal will lead to a fruitless exhaustion of resources in unconquerable situations (e.g., if a professional boxer who has grown older attempts to regain his former championship). The context dependency of development has often been discussed from an evolutionary point of view. Here, it is rather clear that a certain adaptation produced by evolutionary changes (e.g., attributes of a large predator among the dinosaurs) can become useless or even an obstacle for survival if the environment changes dramatically (e.g., Gould, 1989). For the psychological perspective on development pursued throughout this chapter, context should not be viewed as monolithic and deterministic, but as a complex, closely interlinked system; as a concept, it embraces physical, biological, and sociocultural aspects (Bronfenbrenner, 1979; Lawton & Nahemow, 1973).

More than half a century ago, Havighurst (1953) differentiated among three types of developmental tasks that structure the human life course (Heckhausen & Lang, 1994). The concrete list of tasks, which he assigned to different phases of development following the developmental psychology *Zeitgeist* and in particular the work of Erikson (1959), must be seen not only as anachronistic but also as irredeemable in view of its ambition to posit a completely self-contained system of universally valid truths. Nevertheless, the fundamental idea that development is guided by tasks or challenges (Erikson used the term “crises”) retains its validity to this day. Havighurst differentiated among biologically conditioned, socially conditioned, and individually set tasks. A slightly expanded version of this notion can be found in modern approaches that differentiate among different internal and external influences on human development (P. B. Baltes, Cornelius, & Nesselroade, 1979; P. B. Baltes, Lindenberger, et al., 1998; P. B. Baltes et al., 1980). In general, one can distinguish among age-graded, history-graded, and nonnormative influences that can either concern biological or cultural aspects of development (Brandtstädter, 1990, 1998). Although scientists, despite our long-standing interest in this perspective, are

only just now beginning to understand the biological, that is, in particular, the genetic preconditions for development (e.g., Gottlieb, 1998; McClearn, 2003; Plomin, DeFries, McClearn, & McGuffin, 2001), there is a long tradition of studying the social conditions and contextual factors of development. The third category of developmental task (autonomous or self-defined tasks), however, has long been neglected and was not systematically taken into account. Only very recently has an action-oriented perspective on human development been articulated in more detail (Brandtstädter, 1998; Brandtstädter & Lerner, 1999).

Biology and Development: The Interaction between Predisposition and Environment

Obviously, human development occurs in a complex context. Even genetically predetermined developmental trajectories are fundamentally dependent on the right contextual conditions in order to unfold (cf. Anastasi, 1958). This applies not only to the extreme state of biological immaturity in which people are born, making them dependent on supportive conditions (and especially on other people) much longer than other animals in order to reach maturity (P. B. Baltes, 1997; Staudinger & Lindenberger, 2003a); this is also true of the immediate preconditions required for the genetic code to unfold. Without the right conditions in the cellular environment (cytoplasm, ribosomes), the DNA sequence that leaves the cell's nucleus cannot be translated into RNA sequences (which in turn code for the particular amino acids only under specific conditions) and thus does not transmit its information (McClearn, 2003). Thus, genes need specific environmental conditions to develop their potentials. The extreme heterogeneity of the environment, especially on the level of the individual organism, is the basis for the emergence of the impressive heterogeneity of the human phenotype and its developmental trajectories. Conversely, the high level of human variability and plasticity is the adaptive response to the fact that environments are not only heterogeneous but also changeable.

When it comes to determining the strength of influences, be it biological or cultural, the field of behavior genetics is called for (e.g., Plomin & Caspi, 1999). Several studies suggest that interindividual variance of personality traits (i.e., among those who have been investigated) can be explained by genetic variance to an amount of 40% to 50% (Plomin & Caspi, 1999), and this share stays stable or even slightly decreases across the life span (Pedersen & Reynolds, 1998). To put such a result into perspective, however, it must be emphasized that the relationship between genetic factors and the environment is one of complex interaction (which takes place at many different intermediate

levels; Asendorpf, 1999; McClearn, 2003). Among the numerous assumptions on which arguments for heritability are typically based, the assumption of the *additive* effects of genotype and environment in particular is either false or at least drastically simplified and thus misleading (Plomin & Caspi, 1999). Even the activation of genes depends on the environment, including the presence and activation of other genes (Caspi, 1998; Scarr & McCartney, 1983). An illustrative example of the interplay between genetic disposition and environment is the metabolic disorder phenylketonuria (PKU; cf. McClearn, 2003; Plomin & Caspi, 1999; Plomin & Crabbe, 2000; Plomin, DeFries, et al., 2001). Due to the lack of a specific enzyme, the body is unable to adequately break down the substance phenylalanine, which is found in many foods. The unduly high concentration of this substance in turn damages the developing brain to an irreparable degree (according to current knowledge) and leads to a severe impairment and reduction of cognitive abilities. There is no disagreement that PKU is genetically determined, but by maintaining a diet low in phenylalanine, its effects on cognitive development can practically be neutralized (Weglage, 2000). To formulate this in abstract terms, the development of the phenotype (in this case, important cognitive functions) can follow a completely normal development (i.e., no different than for individuals without this disposition) despite an unfavorable genetic disposition if the environment (in this case, nutrition) fits in a differentially adaptive manner. This shows that the question of whether genetic disposition or environment is responsible for the development of intelligence is formulated in misleading terms: It is the interaction (in a technical metaphor, the multiplication rather than the addition) of the two factors that brings forth the phenotype. Precisely because of the defect, the emergence of the phenotype—that is, cognitive development—is *crucially* dependent here on environmental conditions (normally, the type of nutrition has a less severe impact on cognitive development). This example is not intended to contest the significance of genetic determinants (vulnerabilities). Rather, it demonstrates how and to what degree they are relevant (Plomin, DeFries, et al., 2001).

Of course, it is also important not to overlook the fact that environments are, by and large, fairly stable (at least when compared to the average human life expectancy). Independent of the arguments presented earlier, this alone can explain much of why adult personality configurations are so stable: There are few reasons to change, and certainly not to change drastically, and these reasons to change become fewer and fewer as we grow older (Roberts & Caspi, 2003). Ultimately, and not least of all, individuals

choose their environments; they *seek them out* systematically, *influence*, and *change* them (Caspi, 1998; Rowe, 1997; Scarr & McCartney, 1983). The person-environment interactions discussed here can be grouped into at least three categories (Roberts & Caspi, 2003): reactive interactions (people react to the environment as they perceive it), evocative interactions (the social environment reacts to individuals specifically, i.e., in different ways to different people), and proactive interactions (people seek out and create environments, e.g., partnerships). This is particularly true, as the example of PKU vividly demonstrates, when understanding of the mechanisms through which genetic dispositions function informs decisions or intentional changes in environmental conditions (e.g., nutrition in this example; Plomin & Caspi, 1999). To date, empirical study of the interactions (among genes, among environments, and particularly between genes and environments) has barely been attempted, and the majority of studies are still based on an oversimplified and misleading additive model (Gottlieb, 1998).

Social Context Matters: The Interdependence of Individual and Social Developmental Norms

In line with the interactive point of view outlined in the previous section, genetic conditions at best merely demarcate the framework for the individual's processes of change and development (the so-called norm of reaction). Influences of the physical and social environment determine how the individual phenotype is actually shaped and changed. This highlights the influence of social context on individual development. Biological and sociocultural influences can be subdivided according to the earlier mentioned categories, that is, age-graded, history-graded, and nonnormative.

Age-graded biological influences are, for instance, puberty and menopause. *History-graded* biological influences include, for instance, secular trends in physical development such as changes in the average age when menses begins and the dramatic secular trend toward increased life expectancy in the twentieth century (Maier & Vaupel, 2003). Similarly, the availability of food can vary dramatically according to time and region (Elder & O'Rand, 1995) and, either as a result of this availability or completely independent thereof, can differ according to cultural customs of food distribution, preparation, and preferences (Garner, Garfinkel, Schwartz, & Thompson, 1980). Of course, here as well, social influences ultimately explain these trends in development, but in individual development, these aspects appear as biological influences (or developmental tasks). *Nonnormative* biological influences include the results of climate change on development, demanding not only cul-

tural adaptation in the regions affected (e.g., modified hunting practices among the inhabitants of the northern Arctic Circle, storm-proof homes in areas with a higher probability of severe storms) but also individual efforts at adjustment. It is thus important to always keep in mind the embeddedness of development in its particular historical context (P. B. Baltes, 1997). This is true both on the general and the individual level: Both social and biological influences always operate against the background of the particular influences that preceded them. A sudden dramatic change in nutrition has entirely different effects on the development of an individual whose physical development and maturation has already progressed relatively far under relatively good conditions than it does on a newborn baby. Similarly, the outbreak of an epidemic will obviously have completely different consequences depending on whether an antidote or treatment has already been found for the disease.

Let's now turn to sociocultural influences. *Age-graded* social influences are, first of all, explicit social age norms such as the legal regulations governing retirement age (for employees in public service jobs, but in many cases also for standard contractual employment relations), which force active working life to end even if the individual in question feels fully capable and productive and is also motivated to continue working. Implicit social age norms are socially agreed-upon guidelines that define which ways of behaving in late adulthood and old age are deemed appropriate and socially acceptable.

History-graded social influences are events of overarching importance (wars, economic crises, major political changes such as the fall of the Berlin Wall in 1989). The influence of such events depends not only on particular preconditions at the personal level (especially previous experiences and currently available resources) but also on the particular point in the individual's biography at which this experience occurs. A severe economic crisis, for example, could bring about nutritional difficulties and result in specific shortages (e.g., a vitamin deficiency). Adults may experience some limitations due to such events, but usually they are not severely debilitated, whereas newborn babies and especially unborn children in an exceptionally vulnerable phase of physical development may suffer irreparable damage (e.g., in brain or organ development). The same is true for phases of economic decline that create a lack of job training opportunities for young people, in some cases robbing an entire age cohort of their long-term opportunities, whereas previous and following cohorts are affected little if at all. *Nonnormative* social influences, such as an escalating social conflict or the meeting of a person (e.g., a future

life partner or mentor) who will dramatically influence the individual's further development, do not occur on a regular basis and thus can neither be predicted nor planned for.

According to Glen Elder (1994, p. 5), "Overall the life course can be viewed as a multilevel phenomenon, ranging from structured pathways through social institutions and organizations to the social trajectories of individuals and their developmental pathways." Although this is uncontroversial today, it remains unclear how these various levels interact. How do changing societies impact individual development, and conversely, how do individual life courses impact society? One of the most promising hypotheses relating to this question claims that social norms shape individual developmental pathways. The individual life course follows a timetable or calendar that is segmented and geared to follow individual and social (developmental) norms, that is, normative guidelines as to what is and is not appropriate or necessary at a particular time and for a particular person (e.g., Heckhausen, 1999; Neugarten, 1979; Neugarten et al., 1965; Settersten & Mayer, 1997). However, it is useful to differentiate here among several aspects. Social norms and their accompanying sanctions influence individual norms. Individual norms regulate individual intentions and thus individual actions. These, in turn, influence or produce life course events that shape the individual's development.¹

Many developmental norms are merely descriptive norms: It is "normal" to go through puberty at the age of 14, but this normality varies according to time and context. Descriptive norms shape the course of human development, not by implementing prescriptions, but simply as a matter of fact. These norms should therefore be investigated; they may ultimately be proven false, or true only within certain specific historical and cultural contexts. Social tasks constitute a second type of developmental norm: They are prescriptive norms and impose a schedule on individual development by setting times for certain life transitions, for example, school age, voting age, and retirement age. These norms can be violated but not falsified. Some prescriptive social tasks, although nevertheless obligatory, are much less explicit. They involve the subjective experience and evaluation of social prescriptions regarding what is appropriate or necessary at which particular age, and so

on. Four groups of developmental norms can be identified in particular:

1. *Age norms*: "Act your age!" Age norms are prescriptions or proscriptions about behavior to keep people on track or on time in the normative life course or to bring them back into line (Settersten & Mayer, 1997). It may prove useful to differentiate between appropriate or even optimal ages and age margins, that is, upper and lower limits of when it is acceptable to engage in a certain behavior or to decide on taking a certain step. Settersten and Hägestad (1996) define these margins as "cultural age deadlines"; when considering social norms as well as biological realities, such deadlines may be called "developmental deadlines" (Heckhausen, 1999; Wrosch & Heckhausen, 1999).
2. *Sequencing norms*: "Who follows whom?" Some sequences in human development follow a logically or naturally fixed order. For example, one cannot learn to read a clock before having learned to count to 12, understand the concept of hours, minutes, and seconds, and tell the difference between the long and short hands on analog clocks. Reversing this sequence is logically impossible. To cite a further example, a woman must possess certain physical features in order to give birth, and in this case, the reverse sequence is impossible due not to logical but to biological reasons. Other sequences may vary from one individual to another; for example, it is largely a matter of personal choice whether an individual first finishes higher education or first gets married or has children. However, social norms determine the sequence of these life course transitions and thus their respective presuppositions ("You cannot marry before first finishing college and finding a job!").
3. *Quantum norms*: "How much is enough?" One of the most important quantum norms is the socially shared belief about the optimal, minimal, and maximal number of children a family should have. A norm that has been changing rapidly over the past century applies to the number of successive marital partners. Up to the beginning of the twentieth century, the specific number—both minimum and maximum—was one (with notable exceptions, such as Henry VIII in England in the sixteenth century). It seems that, during the past century, two or three is becoming more and more common and thus "normal"; even six or seven successive marriages have become acceptable (at least among film celebrities).
4. *Perceived chronological age* is, along with gender, one of the first categories that can be used to categorize a person at first glance (Neugarten, 1968; Settersten, 1997;

¹ However, it is important to look at the reverse direction as well. The actual course of the individual development influences how the individual evaluates his or her development, and this in turn shapes the individual's developmental norms (Kalicki, 1996).

Settersten & Mayer, 1997). Chronological age is in almost all societies segmented into phases of social age (Neugarten & Hagestad, 1976; Neugarten, Moore, & Lowe, 1965). The transitions between social age phases are often marked by rites of initiation (e.g., to manhood).

The notion of social time is based on the meanings of age, and refers to the ordering of events and social roles by age-linked expectations, sanctions and options. The variable meanings of age represent social constructs, which take the form of age norms and sanctions, and social timetables for the occurrence and arrangements of events. (Elder, 1978, pp. 25–26)

Thus, the concept of social time implies the addition of content to chronological time. Its function is, of course, to segment and structure the individual's life course and, at the same time, to coordinate social functions, roles, tasks, and duties among individuals of different ages.

The resulting age-status systems, in their simplest form, apply a sequence of specific roles to the process of aging and attaches to them specific norms and expectations. An adult is expected to be financially independent, and an older person is expected not to go out dancing to a discotheque at night. These age-related roles are partly explicit (e.g., voting age), partly implicit (e.g., age of first pregnancy). This structure is not deterministic, however, particularly in modern societies. "Social differentiation in complex societies takes the form of plural age structures and timetables, across institutional spheres, and underscores the utility of a multidimensional concept of the life course, a concept of interdependent life paths, which vary in synchronization" (Elder, 1975, p. 173).

Social developmental norms affect the individual's development in various ways. First, they will show indirect effects. Cultural and political policy decisions based (at least partially) on social norms as perceived by decision makers influence the actual developmental courses of individuals throughout society (e.g., retirement age; Jacobs, Kohli, & Rein, 1991). Second, "social institutional constraints provide time-ordered opportunity structures for certain life-course events and thus form part of the 'sociostructural scaffolding' of life-course development" (Heckhausen & Schulz, 1999, p. 81).

Bernice Neugarten (1979; Neugarten & Hagestad, 1976) has aptly termed this structuralizing power of social age norms for individual behavior and development the "social clock." There exists what might be called a "prescriptive timetable for the time ordering of major life events: A time in the life span when men and women are expected to marry, a time to raise children, a time to retire" (Neu-

garten, Moore, & Lowe, 1965, p. 711). The core assumption of the social clock approach focuses on deviations from the social timetable. Individuals who are too early or too late experiencing a certain event or transition suffer consequences. These range from explicit negative social sanctions (e.g., punishment, social exclusion, stigmatization) to intrapersonal problems (e.g., low self-esteem because of negative social comparisons: "I'm still not married!") and reduced interpersonal resources (e.g., reduced social support). This leads to a second argument. If a person is off with respect to the timing of certain life events or transitions, social comparison processes highlight a significant difference between this individual and most of the people around him or her (Brandtstädter & Greve, 1994a; Heckhausen, 1990; Heckhausen & Schulz, 1999; Neugarten & Hagestad, 1976). These social comparisons force attributional processes in order to explain the difference registered by the individual and his or her social environment.

However, modern societies are characterized by a steadily increasing de-institutionalization (Held, 1986; Settersten & Mayer, 1997). One result is a separation between cycles of family development and of work development that is leading to an increased differentiation of life courses. The "normalization" of the individual life course (Held, 1986) through age norms is thus becoming less effective, and perhaps overall less important. Neugarten and Hagestad (1976) speak about an "age-irrelevant society" (see also Neugarten, 1979), in which social developmental norms have decreased in obligation or increased in variance over the past 100 years or so: "Over the last century, everyday ideas about what constitutes the 'normal' biography have become less clear" (Settersten & Mayer, 1997, p. 234). Sociocultural age-related developmental norms vary among cultures and societies to a large degree. To refer to a well-known example, a 14-year-old girl in our culture is a schoolgirl, whereas in other countries, perhaps in India, she may already be married and the mother of her first child. These age norms vary as well *within* particular societies between historical periods and social conditions. For example, the concept of childhood was largely unknown up to the seventeenth century; prior to that, children were perceived—and treated—simply as little adults (Neugarten, 1979).

Action and Development: Intentional Self-Regulation

The very idea that social norms influence individual developmental patterns implies an action-oriented approach to human development. Prescriptive norms are *reasons for actions*, not only causes for behavior (Brandtstädter, 1998;

Elder, 1994; Greve, 2001). There is now broad consensus that human development is not a uniformly operating, irreversible sequence of stages and phases, but a process that individuals themselves actively influence in substantial ways (Ford & Lerner, 1992). This may be termed the “action perspective” on human development (Brandtstädter, 1998, 2002; Brandtstädter & Lerner, 1999). In this view, individuals can be regarded as “co-producers of their development” (Featherman & Lerner, 1985), shaping and altering their scope of action within the framework set by their actual and perceived opportunities and thus substantially steering their own paths through life. Accordingly, not only does the objective framework play an important role in the individual’s development (the opportunities and constraints created by his or her environment and by his or her own competences and deficiencies); personal developmental goals are decisive as well. In terms of both timing and content, individuals structure their own development by recognizing and assigning themselves developmental tasks.

From an action perspective on human development (Brandtstädter, 1998, 2001; Brandtstädter & Lerner, 1999; Greve, 2005), adulthood is characterized by an exceptionally high importance of self-defined and actively pursued developmental goals and tasks. What people do often has far-reaching consequences for them. For example, the decision to quit a job or to move to a new city can impact further development, sometimes substantially altering the individual’s entire future life. The interesting point goes beyond the mere interactional quality of human behavior and human development. In some cases, individuals not only foresee but actually intend the regulatory effects of their actions on their development: These outcomes are the precise aim of the action. I make the decision to study a specific subject and act on this decision to bring me closer to my developmental goal, that is, to become an expert in my chosen field. In other words, action volitionally changes, influences, and contributes to my development.

On the one hand, intervening action can be motivated not only by perceived but also by anticipated developmental problems, for example in a preventive action mode. Furthermore, behavior-initiating discrepancies are not simply passively experienced as “deviations.” In fact, they can be purposefully generated and self-defined, as, for instance, when the orientation toward ideals forms the basis for targeted “upward comparisons” and similar behavioral and developmental incentives (see also Bandura, 1989). Self-defined discrepancies are typically coupled with the individual’s conviction of being able to develop in the direction

of a positive contrasting image; that is, they stimulate individuals to posit corresponding *learning goals* (Dweck & Legget, 1988). Experienced actual/ought discrepancies can admittedly be redressed in different ways. They can be approached through an active problem-oriented altering of an actual situation or, conversely, through the changing of goals and aspirations (Brandtstädter, 1998; Brandtstädter & Rothermund, 2002). This latter mode is, in many cases, overlooked in behavior theory models because the dissolution or reevaluation of goals, the adjustment of demands—although fundamental for behavior regulation—in itself cannot be regarded as intentional behavior (we address this point in detail later).

On the other hand, enabling people to *act* is not only the outcome but the central function of development. All the changes that people pass through between birth and early adulthood that show and constitute their growth can be understood as integral components of the basis, evolution, and expansion of their ability to act (Bandura, 1999). In middle adulthood, it becomes increasingly necessary to stabilize and secure this ability. Although it is possible to progressively differentiate and expand the preconditions and competencies for action and thus to continue developing into later adulthood and old age, the importance of defending the status quo and compensating for the onset of subjective and objective decline in capacities and competences increases at the same time, to safeguard a sense of personal continuity and identity and thus to ensure personal well-being (Brandtstädter, 1999a; Greve et al., 2005; Staudinger et al., 1995).

Intentional behavior is thus of interest to developmental psychology research and theory, not only because of the inherent value in understanding the genesis of intentional behavior and changes in behavior-guiding orientations (goals, value orientations, convictions) throughout the life span, but also to answer the question of what role intentional behavior plays in shaping personal development. Behavior theory concepts such as “personal projects” (Little, 1999), “self-guides” (E. T. Higgins, 1996), and personal life instruments (Staudinger, 1999c) provide promising access to the developmental psychology of adulthood. Here it is fundamental to assume not only that ontogenesis operates automatically, so to speak, on and within individuals, but also that individuals actively shape the course of their own development (see Brandtstädter, 1998, 2001; Brandtstädter & Lerner, 1999). The theoretical focus of an action perspective on human development takes the idea of a transactional influence on one’s own development (for a detailed account, see Roberts & Caspi, 2003; Staudinger & Pasupathi, 2000) one step further. Development and individual action

are related to one another in a causal and at the same time in an intentional way: Through our behavior, we not only actuate factual causal effects, which then partially determine our future lives and behavioral histories; our activities also explicitly aim to shape our development (and indeed, to actively shape the self) in a specific way (Brandtstädter, 1998, 2001). This intentional aspect of developmentally relevant action assumes that individuals have formed conceptual representations of themselves and their lives, that is, notions as to what their lives could and should be. Furthermore, this intentional self-development also means that these feedback processes are not merely registered by the developing person but are subject to systematic considerations and intention formation and thus in a stricter sense are the results of development-related actions (Greve et al., 2005).

At first glance, this seems to contradict the frequently replicated findings regarding the high stability (and thus predictability) of adult identity and personality (Pervin & John, 1999). The available evidence indicates that adults behave so consistently over longer periods of time and also exhibit comparatively robust and increasing stability with age, regardless of these methodological and empirical restrictions. This evidence should not be completely rejected (see Roberts & Caspi, 2003; Staudinger & Pasupathi, 2000). The question is whether it entails that there is *therefore* no development of the adult personality (P. B. Baltes, Lindenberger, et al., 1998). The trait approach, and in particular, the five-factor model, pursues the idea that no ontogenetic development of these basic factors worth mentioning *can* take place at all (after the individual's phenotype unfolds over the course of childhood and into early adulthood). McCrae and Costa (1996, p. 76) consistently argue that the question of personality development is a completely irrelevant research issue.

Several arguments suggest that this cannot be the final word on the subject. To begin with, it must once again be underscored that even optimistic estimates of diachronic stability are accompanied by a considerable amount of unresolved (and thus not stable) variance (a diachronic correlation of $r = .60$ implies a nonpredictable variation of 64%). As we argued previously, an additive (components of variance) model of development probably falls short precisely because it underestimates the interactional quality of the underlying processes. Thus, the stability of manifest behavior is not evidence for the stability of these explanatory variables, and certainly not for the stability of these causal traits (Greve, 2005). Human behavior can, as should become clear in this chapter, appear consistent even for dynamic reasons.

Many experiences and influences within the individual biography shape development in adulthood, not in the sense that they become unalterable at some point, but rather in that the interaction of the accumulated consequences of earlier effects and influences render a radical change increasingly less likely (this is another aspect of the historicity of development mentioned earlier: Development always takes place against the background of its *own* history). In this sense, Roberts and Caspi (2003; see also Caspi & Roberts, 1999) aptly speak of a "cumulative continuity." This cumulative continuity can, however, certainly be intended and deliberately brought about. The allocation of personal resources and efforts changes throughout the life course from a growth-oriented to an increasingly maintenance- and recovery-oriented strategy of personal resource investment (P. B. Baltes & Graf, 1996; P. B. Baltes, Lindenberger, et al., 1998; Staudinger et al., 1995). Development-related actions thus become a decisive factor in explaining the stable and consistent behavior of adults.

Precisely when development-related intentions are oriented toward attaining comprehensive goals that require long-term planning and action (such as career goals), or in a certain sense constitute "insatiable" (Gollwitzer, 1987) intentions (e.g., moral qualities such as faithfulness and honesty, which must constantly be proven), stability of behavior is explainable without having to refer back to a stable *trait* (e.g., honesty). Rather, the observed behavioral stability and high predictability would be explainable by the constant *motive* ("Be honest!"). Kant (1787/1998) employed this argument to point out that stability and predictability are not sufficient to demonstrate the fundamental unchangeability of the cause.

A central research issue, then, from the perspective of the concept of resilience is the relative stability of our comprehensive developmental goals and conceptions—of our self-concepts, life plans, and ideas of who we are and who we want to be—during adulthood. These self-perceptions, self-constructs, and self-plans obviously not only constitute the basis for how we present ourselves as individuals in the social context and therefore convey our personality in professional and everyday life, but also offer the central explanation for the essential consistency of personal behavior in different life contexts and phases. The literature on personality development in adulthood and old age (e.g., Bertrand & Lachman, 2003) has shifted from a documentation of greater stability (McCrae & Costa, 1987; Roberts & DelVecchio, 2000) to an investigation of developmental processes that ensure stability (P. B. Baltes, Lindenberger, et al., 1998; Greve, 2005).

Plasticity of Development: Ranges, Limits, Reserve Capacities

Resilience implies adaptability. A prerequisite for adaptation is the plasticity of human development; that is, it is changeable according to the challenges and opportunities of developmental contexts (P. B. Baltes, 1987; P. B. Baltes, Lindenberger, et al., 1998; Lerner, 1984; Staudinger et al., 1995). Lerner discussed the concept of plasticity extensively some 20 years ago. He referred to Gottlieb's (1998) concept of "probabilistic epigenesis," which describes the fact that the development of each individual within a species is not compelled to follow a single course that is predetermined and identical for all species members, but rather can follow different paths within a "norm of reaction." The more complex the species' structure and the greater the organism's flexibility (e.g., the ability of individual elements of the system to learn, but also variability of interaction between system elements), the broader is the resulting variability of developmental trajectories. Of course, plasticity is evident at multiple levels of analysis. Plasticity has been demonstrated for highly complex phenomena, such as the self. But plasticity has empirically also been demonstrated at very basic levels of functioning. Curtis and Cicchetti (2003) have recently argued that phenomena of neural plasticity can—and have to—be integrated into any future theory of resilience with considerable scope.

The mark of this flexibility and plasticity is the ability to adapt to changed contextual circumstances, that is, to change with regard to specific aspects of the organism (traits, attributes, behavioral tendencies) in order to preserve (stabilize) central characteristics (criteria) of the organism, for example, environment-controlling capacities, general well-being, or health. In this regard, Cicchetti and Aber (1998) have aptly argued that individual flexibility and adaptability is challenged but, at the same time, supported by the fact that changing and varying contexts may demand and thus allow for various ways of adaptation.

Plasticity refers to the latent possibilities of individual development, to a range of possibilities and reserve capacities (Staudinger et al., 1995). As a neutral concept, plasticity comprises processes of falling below as well as of exceeding the normal developmental trajectories, and thus calls attention to processes of developmental optimization as well as developmental psychopathology. The concept of reserve capacity designates the retrievable, maximal individual range of possibilities under optimal developmental conditions (including the best possible support), which is, in a certain sense the positive half of plasticity. Note that the concept of plasticity also includes the notion of its own limits; its latitude is not infinite, not all changes are possi-

ble, and reserve capacity is not inexhaustible. In behavioral genetics (Plomin, De Fries, et al., 2001), this idea is defined through the concept of the "norm of reaction" (Lerner, 1984), which indicates the ontogenetic range of variability that is limited by the genetic makeup of the individual organism, or within which individual biographical conditions produce the interindividual variability and heterogeneity of developmental trajectories referred to earlier.

The concept of resilience focuses specifically on those conditions that ensure that "normal" development is maintained or recovered (we will return to issues of definition in the following section). Based on the understanding of plasticity just introduced, resilience covers those aspects of plasticity that are concerned with maintenance and recovery rather than surpassing natural development. Resilience is a crucial expression and result of plasticity. Resilience-based maintenance and recovery require a lot of adaptation and change. Normal reaction patterns must frequently be replaced by alternative (adaptive) forms of reaction to secure the original "desired" developmental state or course on a higher level. It is this "stabilization through change" that constitutes the salient feature of the phenomenon of resilience.

CONSTELLATIONS OF RESILIENCE: RESILIENCE AS A PRODUCT OF PERSON-CONTEXT INTERACTION

"Resilience is defined as a [person's] achievement of positive developmental outcomes and avoidance of negative outcomes, under significantly adverse conditions" (Wyman, Sandler, Wolchik, & Nelson, 2001, p. 133). Simply stated, resilience describes normal development under non-normal circumstances (compare also Olsson, Bond, Burns, Vella-Brodock, & Sawyer, 2003). In a summary work, Luthar, Cicchetti, and Becker formulate this concept as follows: "a dynamic process encompassing positive adaptation within the context of significant adversity" (Luthar, Cicchetti, & Becker, 2000, p. 543). Although at first glance the basic idea seems clear, the literature, according to Luthar, Cicchetti, et al. (2000), has failed to reach consensus either on a unified conceptualization or (as a result) on a unified understanding of the central constructs (Lösel, Bliesener, & Köferl, 1989; Ryff et al., 1998). Perhaps because the viewpoint is relatively new, a process-oriented notion of resilience has been primarily studied indirectly on the basis of general patterns in empirical findings, rather than measured directly. As will become clear, this is problematic. In any case, it is crucial to first of all examine the concept of resilience more closely.

Remarks on Resilience: Outlining the Contours of the Concept

When discussing resilience as a basic concept for empirical research, we are confronted with a serious problem: the risk of circular logic. Why does one person survive a particular stressful developmental situation so undamaged while another does not? Because she is “resilient.” How do I know and how can I decide that a particular person is resilient? By the fact that she survived this stressful developmental situation unscathed—if she had not been resilient, she would have been (more seriously) damaged by it. Actually, traces of this danger of circular logic can sometimes be identified in definitions of the concept (“protective factors are correlates of resilience”; Masten & Coatsworth, 1995, p. 737). It is possible to steer clear of this danger only by emphasizing that the concept of resilience initially just *designates* a complex process of resistance against stressful developmental conditions. The concept of resilience does not answer the question *why* specific conditions did not produce a negative effect; rather, it formulates this very question.

A more precise *description* of the *phenomenon* of resilience is not easy. To the contrary: resilience is at first glance an issue without an object, even without indicators. Its main theme is (to explain) the *lack* of something: the lack of negative consequences of a developmental experience or constellation that (for other individuals) is stressful, threatening, burdensome, or harmful. If some individuals suffer from the consequences of a certain experience and others do not, it is not clear whether the suffering persons possess or *do not possess* certain attributes, that is, vulnerabilities in the case of the former and protective resources in the latter. Any *difference* between the two (groups of) individuals can be interpreted either way, or so it seems.

Moreover, there are various broader and narrower conceptualizations of the concept of resilience. The terms used to formulate it range from “better-than-expected” development to descriptions of “well-recovered” individuals and “positive adaptation despite adversity” (Arrington & Wilson, 2002; Masten, 2002). Bonanno (2004) explicitly differentiates between recovery and resilience, while other authors even subsume growth processes under the concept of resilience (e.g., Ryff et al., 1998). Growth phenomena, however, even under adverse conditions, may *possibly* refer to resistance capacity, but may also indicate completely different processes, for example, growth stimulation by provoking discrepancies. To subsume these phenomena under the concept of resilience may therefore be misleading. Thus, it is conceptually safer to demarcate the two concepts from each other (Staudinger et al., 1995). Carver

(1998) has proposed applying the concept of “thriving” rather than “resilience” to those growth phenomena that occur under conditions of adversity.

As mentioned above, most conceptions resilience differentiate between the recovery of normal functioning ability subsequent to the suffering of a trauma, and the retention of the ability to function despite the presence of adverse circumstances. It seems to make sense, with regard to old age, to add a third form to these two: loss management (Staudinger et al., 1995). With increasing age, there are further adverse occurrences which bring with them irreversible losses, whether the loss of friends and relatives or of bodily, mental, and/or social functions. Success in dealing with such situations, that is, adapting at a lower level of functioning (but higher as one could have predicted given the adversity the individual has to cope with), which are indeed typical for this age, we would also subsume under constellations of resilience.

Nevertheless, even if the exact conceptual definitions and accordingly the methods of measurement diverge (for a summary, cf. Luthar et al., 2000), it does not mean that resilience is used here merely as an umbrella term encompassing completely disparate phenomena. In fact, there is probably little disagreement about the core meaning (in the sense of the definition outlined at the beginning of this section) of this phenomenon. If there exists basic agreement over the central conceptualization of this phenomenon, but various ways of measuring it for the purposes of scientific study, this can only help to further clarify the concept (regardless of whether the findings correspond entirely or not). On the contrary: the validity of one type of measurement can only be checked through others. As Luthar, Cicchetti, et al. (2000) have pointed out, this does not preclude that the members of the resilience research community should attempt to reach an agreement over a working definition.

The Object of Study: What Actually Is Resilience?

Even more confusion around the concept of resilience is generated through different accents in its content than through differences in its scope. In an overview, Kaplan (1999) describes two basic understandings of the concept. The first views “resilience as outcome,” and here the criterion for the existence of resilience is a (sufficiently positive) result, for example in self-esteem, well-being, health, and so on. From this point of view, resilience is to be explained through various processes. The second understanding sees “resilience as the cause of an outcome,” and here resilience is the concept that helps to explain an

independently defined positive outcome. This source of misunderstanding is important to bear in mind (the concept of adaptation also has a similar double connotation).

With regard to the more frequently pursued second understanding, which we also adopt in this chapter, two general research approaches can be distinguished. The first, a *variable- or process-centered* research approach, investigates how aspects of the person (e.g., traits or abilities) and environment (e.g., social support) are connected with developmental consequences of certain adversities and risks (summarized in Aspinwall, 2001; Masten, 2001). Here we can draw a distinction between additive (cumulative) and interactive (especially mediator or moderator) models (Masten, 2001; Masten & Reed, 2002). There can be little doubt that interactive models are the “heart and soul of resilience” (Roosa, 2000, p. 567) much more than main effect or additive effect models. Each concrete domain can be further differentiated in detail (e.g., by distinguishing compensatory and neutralizing effects). Generally these approaches always consider the interrelationships among different aspects of a person, different people, and between people and the meso- and macro-aspects of their social and physical environments (Arrington & Wilson, 2000).

In contrast, the second, *person-centered* research approach looks at resilient individuals and attempts to determine what sets them apart from non-resilient individuals (“maladaptive personality functioning”; Widinger & Seidlitz, 2002). A classic example of this investigative paradigm is the Kauai longitudinal study (Werner, 1995; Werner & Smith, 1982, 1992, 2001). For this line of research, understanding resilience as a trait is thus logical. This conception is often referred to as “resiliency” (see Masten, 1994; Luthar et al., 2000), a term we therefore do not employ here.

One classic application of this latter approach is the concept of ego resilience (Block & Block, 1980; for an overview cf. also Luthar et al., 2000), which has also been taken up in various ways in the recent literature (e.g., Cicchetti & Rogosch, 1997; Fredrickson, Tugade, Waugh, & Larkin, 2003; Klohnen, 1996; Tugade & Fredrickson, 2004). This personality characteristic is often used with the connotation of a strong orientation toward action concepts like “ego control” and “self-regulation.” Klohnen (1996) summarized this as follows: “resilient individuals have a sense of active and meaningful engagement with the world. Their positive and energetic approach to life is grounded in confident, autonomous, and competent functioning and a sense of mastery within a wide range of life-domains” (p. 1075). Kobasa (1979) has proposed a similar construct (also summarized by Aspinwall, 2001) with the

personality trait “hardiness.” These individuals believe in their own potential to exercise influence and control, are committed to their activities and view change as a challenge (cf. Beasley, Thompson, & Davidson, 2003). Sharply and Yardley (1999) found, for example, that in older people, cognitive hardiness is a good predictor of happiness.

Within this research paradigm, empirical investigation of this phenomenon starts with epidemiological study of these resilience constellations and their empirical characteristics (e.g., Jessor, 1993; Rutter & Rutter, 1993). However, the four conceivable configurations of the two dimensions (high versus low risk, positive versus negative developmental outcome; cf. also von Eye & Schuster, 2000) designed to identify “resilient” individuals are seldom subjected to thorough examination, and particularly not longitudinally. For this reason, interactive or even merely cumulative effects will be harder to identify (and indeed impossible without longitudinal designs) than dominant (practically significant) protective “assets” or risk factors. It should also be taken into consideration that in the investigation of extreme groups, interaction effects could appear masked as main effects (Roosa, 2000).

Asendorpf and van Aken (1999) and Robins, John, Caspi, Moffitt, and Stouthamer-Loeber (1996) are current examples of investigations into personality-oriented resilience (in children as well as youth). However, these studies do not focus on a trait, which would offer a possible bridge to a variable-centered approach (as in the concept of ego-resilience; cf., e.g., also Cicchetti & Rogosch, 1997), but rather on a personality structure. Our argument is that this approach goes only part of the way conceptually: a situational and social constellation must be added to the intrapsychic constellation (cf. in this regard Masten & Garmezy, 1985; cf. also Luthar et al., 2000). Above all, however, developmental potential must be taken into consideration as well: What develops out of a stressful situation (Bonanno, 2004)? These potentials barely become apparent in longitudinal studies such as those by Asendorpf and van Aken (1999), precisely because resilience potential and resources (at least in part) only develop in situations of stress.

In fact, this separation of the research on resilience into person-oriented versus process-oriented approaches (Luthar et al., 2000) is unfortunate since a strictly person-oriented perspective that does not take processes into consideration cannot adequately conceptualize even the very idea of personality (Greve, 2005). Accordingly, numerous conceptions see personality less as a configuration of (stable) traits and more as a dynamic agentic system (e.g., Caprara & Cervone, 2003). A combination of both approaches on resilience therefore seems to be the most sen-

sible (Masten, 2001; Masten & Reed, 2002), also because high-risk groups are few in numbers and thus seldomly encountered. Therefore, without targeted sampling, a process-centered approach would be unable to tap the full potential range of variance precisely in the areas of interest here: stressful and dangerous developmental conditions, and highly “successful” or “unsuccessful” developmental trajectories.

In fact, the differentiation between resilience as outcome, resilience as process, and protective factors can be fairly arbitrary (Staudinger, Marsiske, et al., 1993). Our understanding connects these approaches: here resilience is used as a designation for a developmental process, more precisely as a collective designation for the multitude of processes and the individual and social constellations affecting them, all of which share this characterization because they show a (relatively) positive developmental result despite the presence of unfavorable (adverse) conditions. Resilience is clearly not a simple one-dimensional construction (Luthar, Doernberger, & Zigler, 1993; Olsson et al., 2003; Rutter, 2000). It is obvious that “resilient children” who have developed adaptively in some domains sometimes show completely maladaptive patterns in others (Arrington & Wilson, 2000; Luthar et al., 2000; Tiét & Huizinga, 2002). This alone should clearly demonstrate not only the futility of attempting a comprehensive overall statement about what resilience is, but also and above all, the likelihood that such an enterprise would bear little fruit theoretically. Any given developmental outcome is always conditioned by multiple factors (Rutter, 2000); since it is always the case that more than one developmental path could have led to a given (intermediary) outcome, “the” resilience constellation is pure fiction.

However, the process-oriented definition of resilience (cf., e.g., Olsson et al., 2003) as proposed here brings with it one further problem: from this point of view, resilience “exists” in a strict sense only *if* stressful conditions occur (which are then successfully overcome). Thus, it appears that *potentials* for resilience are by definition impossible (a person- or a trait-oriented approach does not have this problem; Luthar et al., 2000). Once again the answer is that resilience is only the term used to designate a complex occurrence, which we strive to explain through the combination (i.e., interaction) of individual factors (perhaps including certain traits; Roosa, 2000). Provided that these types of factors are identified, their effects can be investigated separately and in combination or interaction (preferably in prospective designs). Frequently the concept of adaptation is contained in the definition as well (e.g., Arrington & Wilson, 2000, p. 225; Luthar et al.,

2000, p. 543; Masten, 2001, p. 228; Masten & Reed, 2002, p. 75), making a circular logic in the explanation almost unavoidable. Especially if “adaptive” is used only as a synonym for “positive outcome” (e.g., Affleck & Tennen, 1996), the potential explanatory value of the concept is lost. This explanatory value consists precisely in the fact that a certain type of adaptation (e.g., a change of semantic associations) of certain structures (such as the availability of self-defining attributes) in a certain way (e.g., through change in the probability of an affective priming of certain information) is causally responsible for a certain positive outcome (e.g., subjective well-being; e.g., Greve & Wentura, 2003). The scientific challenge for psychology is then to more precisely explain this developmental process with reference to concrete self-regulatory mechanisms and processes, that is, to uncover what exactly is concealed behind the macro-phenomenon of resilience. This implies among other things that “resilience” does not denote a real, ascertainable, or measurable entity or anything similar (Tarter & Vanyukov, 1999), and thus not a trait.

From our point of view (and in opposition to sharp critique: Glantz & Sloboda, 1999; Kaplan, 1999), resilience is an unusually useful concept. This is not because it designates a construct with special explanatory power; as we just argued, resilience designates an *explanandum*, not an *explanans*. Resilience is important, first of all, because it can describe a particularly interesting group of developmental phenomena (i.e., developmental trajectories), the identification and explanation of whose common features poses a challenge—but a potentially fruitful one—for developmental psychology. These phenomena could be a central reason for the impressive career of this concept in current debates, since it highlights developmental trajectories that are not only unpredictable but also even tend to run counter to theoretical prediction.

Second, the concept of resilience is especially useful and fruitful because it marks and can further stimulate a change in perspective in developmental psychology as well as in developmental psychopathology. According to the view entailed in the concept of resilience, development may frequently occur even when at first glance no substantial changes are observed. This may be able to tell us more about the processes that produce the changes than a perspective focused exclusively on observable changes. Stability and stabilization as developmental phenomena are closely linked with resilience. It thus follows that not only can resilience validly be applied to individuals (perhaps not even primarily to them); it also can (and should; Glantz & Sloboda, 1999) be applied to constellations, that is, the relation between risk

factors, processes, and positive outcomes (Staudinger & Greve, 2001).

Third, in order to understand and explain phenomena of developmental psychopathology, the concept of resilience may support—and even shape—this endeavor in several respects. It reminds us that sometimes potentially harmful effects can be overseen or underestimated because the individuals “show” resilience. This may shift the focus when trying to explain certain maladaptive reactions from the harmful impact to the lack of resources. A proper understanding of processes and constellations of resilience can also support our search for effective interventive and preventive measures. One aim of research should, for instance, be the development of environments that support resilience. And finally, the life span concept of resilience pursued in this chapter also highlights that individual and social possibilities to overcome developmental adversities—that is, the danger of developmental pathologies—are richer than obvious at first sight and that they are present throughout the life span.

Successful Development: The Problem of Universal Evaluation Criteria

A particularly prominent and at the same time serious problem with the concept of resilience is that it requires two value judgments to be made before the phenomenon can be identified at all (Luthar et al., 2000, p. 549ff.; Masten, 2001; Masten & Reed, 2002, p. 75; Rutter, 2000; Tiét & Huizinga, 2002). On the one hand, the developmental situation must be judged to be adverse, stressful, and potentially dangerous.² At first glance, one might assume that this is statistically possible (e.g., when “the majority of the affected persons developed negatively under such conditions”).³ However, this would by definition exclude the possibility that a majority of the population possesses resources of resilience which is completely plausible in the case of specific types of adversity (e.g., burdens or dangers for development that have existed for a longer period);

the adaptation by groups or populations to relatively stable risk factors is, briefly stated, the principle of evolutionary development and thus the concept of evolutionary adaptation (Barkow, Cosmides, & Tooby, 1992). Accordingly, Tiét and Huizinga (2002) apply the concepts resilience and adaptation largely interchangeably. This is also the principle of biological immunization against a virus: the virus remains dangerous—it has not been rendered harmless or even become extinct—even if the majority of (surviving) persons in whom it is still detectable are now immune. Actually, several studies are now arriving at the conclusion that resilience is a normal phenomenon (Masten, 2001). Therefore the possibility of calling widespread immunization “resilience” (simply because the majority of people are immune at a given time) cannot by definition be ruled out. This means that one would have to define risk factors as well as assets in other than statistically descriptive ways. Referring to prototypical examples, however, is also problematic. There may be indisputable cases (a serious accident on the one hand, a loving grandmother on the other; Masten, 2001), but these may not be indisputable under all circumstances (the grandmother’s loving care may be perceived by the grandchild as incomprehension, while the accident, even if it was the cause of injury, may have prevented a much larger catastrophe, such as the boarding of an airplane, which then crashed). On the other hand, most cases are not even indisputable at first glance (under normal circumstances), but rather part of a continuum of favorable and less favorable events that must be classified individually (Masten, 2001). However, this is only possible within the framework of a developmental theory that specifies normal development against which negative deviations can be identified.

This implies that it is impossible to avoid making a value judgment when determining “resilience” and that the very concept of resilience is based on a developmental theory that includes a theory of “good” and “optimal” development. This leads us to the second value judgment: it is necessary to evaluate the resilience of individuals affected by these adverse, unfavorable, or even hostile conditions as “good,” “successful,” and so on. Analogously, the approach of developmental psychopathology (summarized in Cicchetti & Rogosch, 2002) also needs to be able to make recourse to a developmental theory based on (evaluative) definitions of criteria for normal, successful development. One can also distinguish between internal (e.g., health, cognitive, emotional) and external (e.g., behavioral or social) aspects (Staudinger & Greve, 2001; Tiét & Huizinga, 2002). The present (outcome-oriented) literature has put forward a considerable variety of criteria on which to base

²For example, Arrington and Wilson (2000, p. 223) suggest applying the concept of risk to groups and vulnerability to individuals. Although this appears to be helpful, it would be practically inconsistent, as individuals also face risks, that is, external constellations of conditions, which can lead, in the absence of individual protective factors, to maladaptive development and developmental disruptions.

³The second value problem (see later discussion) is implied by the first in this case as well.

this value judgment (for an overview, cf. also Olsson et al., 2003).⁴ Apart from this lack of uniformity it is conceptually unclear what a generally agreed upon definition of “developmental success” could look like. Making use of this statistically is particularly problematic, since again here the possibility cannot be excluded that the majority of the persons observed at any given time responded maladaptively. Both value judgments thus point toward a theory of *successful* development (Greve, 2001). The idea of positive psychology (Aspinwall & Staudinger, 2003; Seligman & Csikszentmihalyi, 2000; Snyder & Lopez, 2002) implies from the developmental psychological perspective the conception of “optimal” or at least “successful” development (P. B. Baltes & Baltes, 1990; Brandtstädter & Schneewind, 1977; Greve, 2001).

Many authors, in sketching the contours for their definition of successful development, make reference to the successful accomplishment of developmental tasks, according to specifically defined criteria for each task (e.g., Masten & Coatsworth, 1995; Masten & Reed, 2002; Wyman et al., 2001). The central idea here is to formulate age-specific tasks that define normative standards, which in turn form the basis for judging the success of individual development in relatively differentiated terms. This nevertheless probably only constitutes a temporary solution, for three reasons. First, these types of lists must always remain unfinished (due to cultural and historical changes, but also to the self-designated developmental). Second, the normative specifications of the goals contained in such lists can always be subjected to critique. (Is, for example, marriage a *criterion*, that is, a necessary condition for successful development? Obviously not always and everywhere.) Third and above all, these developmental goals in many cases implicitly or explicitly contain the acquisition or construction of aspects that must be at the center of any theory of resilience (e.g., as resources or assets)—identity, self-worth, self-efficacy, stable social relations, and so on. More explicitly normative models such as Erikson’s well-known theory of psychosocial development (1959, 1984) are either empirically untenable (why should there be exactly eight stages, everywhere, at all times, for everyone?) or—precisely because of the normative claims—in principle untestable, and thus unsuitable as a measure of successful development. The classic

functionality criteria, moreover, are possibly not applicable to all age groups alike (Widinger & Seidlitz, 2002). Here again as with other aspects, it can be argued that in the case of older people, other measurement standards should be applied. This is clear not only for personality characteristics (Widinger & Seidlitz, 2002), but also for other criteria. For example, the classic criteria of depression (changes in sleep or sexual behavior, also possibly without the presence of depressive trajectories) may be age-correlated, which raises the demand for development of age-sensitive instruments of measurement. This again calls attention to the exigency of a theory of successful development that explicitly addresses this need.

In contrast, however, many scholars in the field of developmental psychology take the view that (for the reasons indicated above) the articulation of concrete, content-based criteria—as they were referred to in numerous classic psychological approaches (cf., e.g., Kohlberg, 1971; Maslow, 1970; for a summary, see, e.g., Ryff & Singer, 2002), and still often continue to be called uncritically (e.g., authenticity; Harter, 2002)—can no longer be defended (e.g., P. B. Baltes, Glück, & Kunzmann, 2002; M. Baltes & Carstensen, 2003; Staudinger et al., 1995). This is especially true when referring to middle-class norms and to white, male standards (M. Baltes & Carstensen, 2003). Concepts that impose substantive value judgments cannot, according to the objections, be postulated as essential to a positive psychology without additional (value or normative) premises. It is necessary to provide at least a functionally or otherwise empirically (scientifically) grounded argument, which in turn must relate back to a criterion of developmental success. Thus, a life span perspective on developmental psychology is focused less on concrete indicators (e.g., happiness, social integration, authenticity) and more on a balance between internal needs and aspirations on the one hand, and the demands of the environment on the other (Freund & Riedinger, 2003). According to this view—at least in our increasingly fast, increasingly changing, increasingly complex world—the (hopeless) search for generally agreed, concrete criteria is less important than the “delineation of a behavioral system that promotes as a ‘whole’ the continued adaptation to and mastery of new life circumstances” (P. B. Baltes & Freund, 2003, p. 25).

In fact, the relationship between empirical description and explanation on the one hand and positions based on value judgments or normative demands on the other is more complex. Even if empirical facts do not constitute a *sufficient* condition for passing judgment, they are nevertheless usually *necessary* conditions (Brandtstädter & Schneewind, 1977). Whenever practical decisions are

⁴It is perhaps worth mentioning that the problem is often not even recognized as a *problem*. Thus, Widinger and Seidlitz (2002) gather examples of positive (e.g., conscientious, efficient) and negative (e.g., anxious, negligent) traits of people without even discussing that the two groups are “positive” or “negative” depending on the context and valuation measures used.

made, empirical assertions of fact (typically in the form of expectations) are entailed. The demand to encourage active mobility and autonomy among older people presupposes that this actually serves to maintain their mobility and autonomy and thereby promote their general well-being; this assumption is empirically testable. Science thus plays a key role in answering the question of successful development, even when the criterion for this “success” must be defined pre-scientifically.

The search for *universally applicable* criteria—regardless of people’s particular individual, cultural, and historical circumstances—appears unpromising, however, if only because people’s “success” from the action perspective on human development depends not least of all on what they judge to be successful *themselves*. Brandtstädter and Schneewind (1977) pointed out that objective definitions of the meaning of “optimal development” and the recourse to purely subjective evaluation criteria are equally inadequate (partly because both cases always lead to a relativization of current [perceived] social standards and benchmarks; Brandtstädter, 2002, p. 383).

These considerations point toward a solution to the criteria question. Beyond the fulfillment of basic vital conditions, the preconditions for successful development are evidently meta-competencies and meta-resources which ensure that individuals use opportunities and support to compensate for deficits and vulnerabilities and are able to actively influence their development within the framework of the options currently and theoretically available to them (Baltes & Carstensen, 2003; Brandtstädter & Schneewind, 1977; Greve, 2001; Staudinger, 1999b). Human ontogeny is characterized by the fact that it is shaped over long stretches by *us*, by our goals in life, and by our self-concepts. The individual biography, which constitutes our lives, is admittedly also the result of the constraints and conditions we encounter and the preconditions we start off with (and only sometimes are able to influence). Since we navigate through life with equal measures of intention and accident, a convincing model of successful development must take two separate aspects into account: the possibilities (and limits) of individual and social control over our own development, as well as the resources for managing and coping with coincidental and unpredictable events, be they positive or challenging (Brandtstädter, 2002). If this observation is correct, two aspects of human development in particular hold a key function in explaining the aforementioned meta-competencies. The option of seizing opportunities and actively influencing and controlling our own development is centrally dependent on self-regulatory competencies.

Autonomy: Preconditions and Processes of Self-Development

If human development is essentially a product of culture and a result of actions (P. B. Baltes, 1997; Brandtstädter, 1998; Staudinger, Marsiske, & Baltes, 1995), then the ability to take action—that is, to select developmental goals, make decisions, form intentions, put them into action, and if necessary also overcome obstacles and revise strategies—is an essential precondition for successful development (Brandtstädter & Lerner, 1999). Heckhausen (2003; Heckhausen & Schulz, 1995) has therefore passionately argued in favor of regarding primary control as an actual universal developmental goal—and thus as a criterion of successful development. We do not support this strong position (“ultimate criterion,” p. 387) above all because primary control depends just as much on subjective attributions of relevancy and significance as on individual standards of evaluation. Which areas I want to control and what degree of “personal control” I am satisfied with (or consider adequate) will depend not least of all on my individual evaluations, which constantly change over the course of development, also in dependence on my development trajectories (Brandtstädter, 1998). However, it is without doubt accurate to say that striving to influence the environment (relevant to life) is a primary motive for the action of human and living beings in general. Successful action requires not only the specific competencies necessary to carry out the selected action, but also that these competencies are adequately represented in the individual’s self-image. Any given action, including development-regulative action, can only succeed if the person taking it has a sufficiently realistic image of him or herself. This applies not only to the present real self, but also to an adequate representation of the possible self (Markus & Nurius, 1986), that is, of the options and possibilities the individual envisions for him or herself. At the same time, this is also a precondition for making a suitable choice from among the possible developmental options (Ryan, 1993). The self thus has an integrating, “orchestrating” function for human development (Staudinger, Marsiske, et al., 1995). This bestows particular significance on processes that ensure the integration, continuity, stability and (sufficient) reality orientation, and simultaneously sufficiently positive (optimistic) shading of the self (Greve et al., 2005).

Coping

This brings us to the second point. In many cases, personal coping resources are a precondition for allowing development to take a successful course, as outlined above. Coping in general is, today, conceived as a process (in contrast to a

personal disposition or current state) by which individuals manage the challenging, threatening, or harmful demands placed upon them (Lazarus & Folkman, 1984; Montada, Filipp, & M. Lerner, 1992). Thus, the concept is a neutral one that includes active, “problem-focused” efforts as well as re-active (“emotion-focused”) adaptations (Lazarus, 1991). Going one step further, human development in general may be regarded as a hierarchical, interactive sequence of micro- and macroscopic coping processes. Skinner and Edge (1998) have argued that coping and development are inherently interconnected. No account of development is complete without a consideration of how individuals adapt to adversity and master challenges. Developmental tasks are challenging discrepancies between the (perceived) current reality and a normative standard (e.g., ideal self, personal goal or value, social norms, and so on; Brandtstädter, Wentura, & Greve, 1993). Coping brings into focus the question of how the individual deals with a particular set of demands. Moreover, while current coping processes and resources are shaped by developmental conditions, coping reactions can also act as forces in creating future development. The distinction between short-term or current adaptive processes (“coping”) and long-term or diachronic adaptation (“development”) appears all the more arbitrary and fuzzy the more closely a specific change is observed.

Development essentially consists in upholding and implementing the individual’s capacity to adapt to discrepancies in new situations and developmental tasks, while seeking (via assimilation or accommodation) to solve—or dissolve—the discrepancies that generate crises or create burdens and seem unavoidable in the long run (Brandtstädter & Rothermund, 2002). Thus, successful development implies a progressive adaptation that simultaneously maintains or indeed expands this plasticity and adaptivity. As far as we know today, this is possible—and usual—even into the late years of very old age (P. B. Baltes, 1997). This leads to the seemingly tautological statement that successful development essentially means ensuring that development, that is, progressive adaptation, will always be possible and really will occur.

Resilience and Coping: Two Sides of the Same Coin?

The theoretical and empirical relation between resilience and coping seems to need some further consideration. There appears to be a considerable overlap between the two concepts, both at first glance and upon closer inspection. Sometimes, the terms are even used synonymously. We suggest to avoid such an all encompassing notion of “coping,” but rather suggest that coping is an important facet of a re-

silience constellation but not the same as resilience (see also Ryff et al., 1998). Coping comes into play when investigating the process component of resilience and there it constitutes an important part (Beasley et al., 2003). Coping, usually structural, lacks the constellation aspect of resilience that includes risks and protective factors on the one and developmental outcomes on the other hand. The coping literature has a much clearer focus on the process component and does also not include resources such as intellectual capacity or financial resources (e.g., Lazarus, 1993). In other words, coping is an important process resource of a resilience constellation (see also, Staudinger & Greve, 2001).

Furthermore, coping in the strict sense describes the management of stress factors (at least in the classic use of the term which characterizes, e.g., Lazarus’ approach) that overtax an individual’s own immediately available resources. The term resilience, however, evidently implies successful management.

Of course, resilience may comprise processes that can be also described as coping. In particular, two basic ways of dealing with stressful experiences have been distinguished that are also of particular importance for theoretical and empirical work on resilience. First, there are the *active efforts* undertaken to master critical events. Here, coping means reducing the actual/ought discrepancy through problem-oriented action that aims to end the adverse situation. Second, coping is understood as the *adaptive adjustment* to a course of development experienced as irrevocably negative, an adaptation, which eventually leads to regaining well-being and life satisfaction. The subjective perception of the critical situation’s controllability is thus decisive for the “selection” of the coping tendency. The question of what is adaptive has to be answered with regard to the particular situation. For instance, so called “regressive” coping activities such as “giving up responsibility” have been found to be of adaptive value if the situation does not allow for change but rather asks for accepting the loss (cf. Staudinger, Freund, Linden, & Maas, 1999). The same may be true for “defensive” strategies such as denial.

The subject of “coping in old age” can be discussed from two perspectives. First, it is a question of specific events to be managed in old age: *coping with old age*. As referred to above, common stereotypes and a series of findings indicate that adverse problem situations begin to accumulate in later adulthood. Physical and mental performance tend to decline, serious illness and disabilities occur (with a higher probability than in younger years), the remaining years of life decrease, career goals disappear due to retirement, important friends and relatives die. The fact that these problems are increasingly characterized by leads us to the

second aspect. With increasing age and the changing problems that accompany it, the means of *coping in old age* change as well. Adaptive reactions and processes that do not actively solve but “dissolve” the problem, that is, remove it, become increasingly promising and probable (Brandtstädter & Renner, 1990; Brandtstädter & Rothermund, 2002). It is interesting to note that the overwhelming majority of individuals in late adulthood and old age are apparently successful in “managing” crises (including the negative aspects of aging) in this way (Brandtstädter & Greve, 1994; Brandtstädter & Wentura, 1995; Staudinger, 2000; Staudinger et al., 1995).

In cases where individuals face losses and deficits, they actively confront them in a variety of ways. The model “selective optimization with compensation” (P. B. Baltes & Baltes, 1990; Freund, Li, & Baltes, 1999; Staudinger & Lindenberger, 2003) examines these strategic responses to losses that threaten to occur or already have. Active forms of coping are characterized by adherence to the standards and the value and goal orientations under threat. However, not every actual/ought discrepancy can be reduced through active, and in particular proactive problem solving. Nor can definitive failure or irreversible losses be compensated for by delegation. The possible emotional consequences, which may—depending on the subjective importance of the life domain affected—be dramatic and range from desperation and grief through hopelessness to depression, can, however, be regulated or possibly even avoided entirely through adaptive coping reactions. One characteristic aspect is that the threatened “ought” values are changed to such that the discrepancy is reduced or entirely resolved. Adaptations of the system of personal values and preferences, reinterpretations of stressful problem situations, changes in perspective and deliberate (downwards) comparisons are typical examples of processes that contribute to resolving the actual/ought discrepancy, thereby reducing the adverse effect of this discrepancy on well-being and life satisfaction (Brandtstädter & Renner, 1990). The end point of these “accommodative” processes (Brandtstädter & Greve, 1994a; Brandtstädter & Wentura, 1995) is that the individual’s self-image, and the image of his or her goals and situation in life is altered and no longer contains the negative actual/ought discrepancy.

Coping episodes can be typically reconstructed as an interlocking combination of complementary active-strategic *and* accommodative processes, as the two modes of coping may be used to achieve different goals. Not least, modifying personal goal structures and preferences can also make it possible again to exercise control over highly valued

goals, thereby also (subjectively) enabling active efforts that previously appeared pointless and would have taken up valuable resources unnecessarily (Brandtstädter & Rothermund, 1995). This is a central function of the aforementioned selection processes (P. B. Baltes & Baltes, 1990). For instance, in old age and under circumstances of physical constraints, it may be highly adaptive to give up independence, that is, move into assisted living quarters or have permanent help come in. By choosing dependence in old age we may gain powers that we can use for keeping up friendships or for pursuing other interest (M. Baltes, 1996). The reduction of aspiration levels can be similarly classified. Being irreversibly unable to fulfill a specific criterion of physical fitness—for example, climbing several flights of stairs with ease—due to aging stimulates accommodative coping. This may, however, result in a more age-appropriate definition of physical fitness, which individuals then indeed actively pursue. Equally, compensation processes also call for active *and* accommodative regulations. If otherwise effective repertoires of action fail to achieve goals or maintain standards, the individual seeks alternative paths of action, possibly involving compensatory aids (for instance, a hearing aid). The precondition for this step, however, is an acceptance of irreversible losses on a subordinate goal level: only individuals who can cope with a self-definition as hard of hearing, and thus accept a hearing aid, can continue to communicate (relatively) effortlessly.

Coping in old age does, of course, have its limits. Health problems are often neither curable nor can they be looked at in relative terms. Permanent eyesight restrictions or the loss of a long-term partner, for example, can only be compensated for to a certain extent and only partially emotionally alleviated. Not least in very old age, there is an increasing probability of deficits and losses that no longer appear “manageable.” The perspective of coping and regulation dynamics must not seduce scholars to assess negative emotional reactions as “failure.” Quite the opposite: Only a more comprehensive concept of coping opens up the possibility of recognizing grief and desperation reactions as facets of a regulation process that enables individuals to live with even difficult situations and crises.

The observations described here illustrate that the coping theories relating to late adulthood and old age clearly include functions and regulative processes that can help to explain the phenomenon of resilience. We will therefore go into somewhat more detail on the models of development regulation mentioned here in a later section. For the purpose of our argument in this section, it is initially only important to recognize that coping processes are clearly a

constitutive element of resilience, particularly in cases where they include adaptive processes that are characteristic of later adulthood.

Resilience as an Issue of Empirical Research

Having more clearly outlined the concept of resilience that we intend to use here through the discussion up to this point, it is easier to survey and evaluate the research landscape. Early studies (starting with the work of Rutter, Garmezy, and Werner in the 1970s; for an overview, cf., e.g., Kaplan, 1999; Luthar et al., 2000; Masten, 2001; Masten & Coatsworth, 1998; Masten & Reed, 2002; Rutter, 2000; Ryff et al., 1998; Tiét & Huizinga, 2002) focused in particular on psychopathological conditions in childhood (including biological risk factors, e.g., parents diagnosed with Schizophrenia, or perinatal stress), social risks (e.g., poverty or other social disadvantages) and traumatic biographical stress during childhood (e.g., sexual abuse, physical maltreatment). The phenomenon has also been examined in very extreme cases of stress, such as among Holocaust survivors (Greene, 2002) and among parents of children with disabilities (Heiman, 2002). In general, two types of studies can be distinguished. One kind of studies is based on very low sample sizes but with highly nuanced observations or qualitative data (e.g., Felten, 2000). The other kind of studies is rather large scale studies using quantitative assessment and pursuing almost an epidemiological approach (e.g., Jessor, 1993; Masten, 2001; Rutter & Rutter, 1993).

Broad-based research activities as early as the 1980s indicate increasing attention on the phenomenon of sound development in the context of multiple life stressors and adversities (for a summary, cf., e.g., Masten & Reed, 2002; e.g., Wyman et al., 2001). These studies were initially concerned with identifying resources available to children under such conditions (for a summary, cf., e.g., Kumpfer, 1999), and primarily with developing and testing theoretical models specifying the relation of these resources to the processes of adaptation. Research on the development of family dynamics also demonstrates a clear trend toward a resilience-oriented perspective (cf., e.g., the meta-analysis of Allen, Blieszner, & Roberto, 2000). One example of prototypical resilience research is the study of various prototypical development courses (cf. Masten & Reed, 2002 on the basic approach) regarding antisocial behavior (e.g., Loeber & Stouthamer-Loeber, 1998).

Studies of resilience highlight above all the considerable differences between individuals in their responses to ad-

verse circumstances. Although extreme situations (e.g., severe abuse) exceed the resources and reserves of almost all those affected, there is a considerable breadth of variation in the forms of reaction, and thus of development, that negative circumstances induce. The existence of a large number of protective resources or assets has been proven empirically, although many of the combinations thereof (cf. regarding children, e.g., Masten & Reed, 2002, p. 83) have not been subjected to theoretical systematization (Masten, 2001). However, the most important problem is that quite often aspects that are psychologically directly or indirectly influential (e.g., self-efficacy, intellectual capacities) are combined with variables that merely point to underlying mechanisms rather than being of explanatory value themselves (e.g., socio-economic status). Often it is unclear whether a given variable belongs to the former or the latter. For example, gender is in most cases a variable of the second category, while parenting behavior may be assigned to either category depending on how it is defined and measured. Consequently, risk factors are usually risk *markers*. As Rutter has aptly noted, it is of crucial importance to differentiate between risk indicators and risk mechanisms (2000, p. 653). The empirical detection of risk markers (indicators, at best) is based on group data; thus, a risk in this perspective is an estimated probability that a member of a certain group (or population) will exhibit a maladaptive developmental outcome. Risk markers thus make it possible to predict (with a certain probability) the specific (maladaptive) developmental course. Correspondingly, meta-studies (e.g., Norris et al., 2002) also indicate little more than a very heterogeneous combination of risk and protective factors on very differing theoretical levels.

Further, there are a number of variables that empirically demonstrate differences with regard to their protective value depending on given contextual circumstances. An interesting example of this phenomenon is the connection of resilience to self-enhancement (for a summary, cf. Bonanno, 2004), and thus to self-esteem (cf. Masten & Garmezy, 1985). On the one hand, self-esteem (at least of a moderate kind) appears to be a resource (moderator variable) for coping with threats and stress (e.g., Cicchetti, 1997; cf. also Aspinwall, 2001). On the other hand, reduced self-esteem is frequently a consequence of stress and threats (e.g., in victims of school violence; Greve & Wilmers, 2003). Simultaneously, however, self-esteem is likely to be a positive precondition for mobilizing or even simply accepting social support (and thus a mediator variable for problem management). Yet other studies indicate that high self-esteem is not always positive per se (cf.

Baumeister, 1993; Crocker & Park, 2004). Two aspects may be important when trying to integrate those seemingly contradictory findings. First, the functionality of self-esteem does not follow a linear function, that is, if self-esteem surpasses a certain level, it turns into being dysfunctional (which by the way is also true for optimism; cf. Baltes et al., 1998). Second, it is important to consider the process dynamics of self-esteem regulations that is, for instance, how robust or vulnerable is a given level of self-esteem (e.g., Greve & Enzmann, 2003). The protective significance of self-esteem can therefore presumably only be clearly formulated when clarifying which structural and procedural bases for self-esteem can be protective, and which can be dangerous, under what specific (individual and situational) conditions. Moreover, empirical evidence that positive self-esteem co-varies with successful development presents theoretical problems simply because an adequate level of self-esteem will always be a central *criterion* of successful development (no matter how it is defined). In any case, significantly low self-esteem cannot, for conceptual reasons, occur in conjunction with “successful” development, let alone be considered a defining characteristic thereof. Some studies therefore also construct their examination of resilience around the factor of self-esteem (e.g., Lösel, Bliesener, & Köferl, 1989; Tiét & Huizinga, 2002). Nevertheless, it is also conceivable that other aspects of successful development, such as social integration, competence in pro-social behavior, empathy, might themselves be explained by self-esteem. The complex role of self-esteem thus appears to be an empirical issue; a differentiated study of state and trait components is likely to play a key role in this context.

When we turn to older people in particular, we face the problem that diachronic reflexive interactions are characteristic of the phenomenon of resilience. Thus, the question of whether disengagement or continued activity indicates successful aging is wrongly phrased, not only because (under certain circumstances) *both* can obviously be defined as “successful” (Freund & Riediger, 2003); it is also misleading because social engagement as well as social withdrawal, seen diachronically, can be both products and producers of well-being (or dissatisfaction and suffering). For example, if sickness forces me to reduce my social contacts (e.g., because I am less mobile, hard of hearing) and I am unable to compensate for this in other ways (e.g., through closer relationships with family members, e.g., grandchildren, or through pursuing a hobby at home), this may then (and *only* then) trigger a progressive downwards spiral into increasing social isolation. Conversely, the de-

liberate continuation of social activities that consume all available energy and resources can indicate unsuccessful regulation of development, rigid intractability, and reality avoidance, and can also prompt high medium-term costs in terms of satisfaction (and health).

Although there have been repeated calls for theoretically guided research dealing with precisely *these* issues (e.g., Luthar et al., 2000; Masten & Reed, 2002), this may well constitute the most important desideratum of resilience studies at present. One important path that has been pursued rather seldom to date, particularly in the context of later adulthood and old age, is to design experimental, or quasi-experimental, scientific models to accompany systematically planned intervention studies (cf. Masten & Reed, 2002).

Resilience Is Ordinary and Universal

In general, all the evidence currently indicates that even extraordinary resilience results from “ordinary” processes. There is no reason to assume at present that psychological resistance and the ability to overcome or cope with stress, difficulties, and adversities require special individual skills or conditions only attainable or available in exceptional cases. In fact, in any given case, just one of a multitude of possible configurations or combinations (and not any specific combination) of protective factors appears to suffice to overcome even extreme stress and adversities (Masten, 2001). Bonanno (2004) argues that resilience is far more widespread than assumed, even in cases of extreme loss and traumata. An indication of this is apparently that, roughly estimated, at least 50% to 60% of all adults have been exposed to an instance of stress which can be described as traumatic at least once in their lives, but only one-tenth are reported to have developed PTSD symptoms (Ozer, Best, Lipsey, & Weiss, 2003). The figure is less than 20% even for victims of serious violence (for a summary, cf. Bonanno, 2004). Bonanno, Papa, and O’Neill (2002) also argue that resilience occurs much more frequently than is often assumed. They give the example that grief (e.g., after the death of friends or relatives) does not occur frequently, which—in contrast to numerous myths from certain schools of therapy—can also be seen as a positive indicator (Wortman & Silver, 2001). Furthermore, the psychology of the self has provided firm evidence of a multiple self-system that adapts to current demands, not only over the course of life but also from situation to situation, without losing its continuity (and thus identity), again confirming that phenomena of resilience are an everyday occurrence. Structurally similar phenomena also ensure personal continuity

in cases of (what initially appear to be) serious losses or stress. We have to realize that resilience indeed is a normatively occurring phenomenon. It is not confined to (but does not exclude) spectacular circumstances. For instance, in the realm of cognitive development across the life span resilience occurs normatively; that is, the rather strong decline of fluid abilities during adulthood and into old age does not undermine overall cognitive functioning (Baltes, Lindenberger, & Staudinger, 1998). It is through the acquisition of a great number of bodies of knowledge that the decline in speed of processing and in coordinating information is compensated.

The question is, which mechanisms—aside from the coping processes discussed above—can give rise to resilience? For example, adults have been shown not only to increasingly focus on positive affects, but also to use cognitive-affective complexity as a possible buffer (Labouvie-Vief & Medler, 2002). Self-complexity (Linville, 1985, 1987) could be one protective resource (cf., e.g., Affleck & Tennen, 1996). The basic idea is that, if one aspect is under threat, a differentiated self in which various domains (semantic or affective) are not too closely networked, protects many other areas from being affected by this threat. In a meta-analysis, however, Rafaeli-Mor and Steinberg (2002) come to the cautious conclusion that this buffer hypothesis is not very well supported, but the extreme heterogeneity of the findings (and of the quality of the studies involved) does not permit a firm conclusion. It seems clear, however, that complexity by itself does not do the trick but needs to be complemented by integration at the same time and the various self-aspects need to be evaluated positively (cf. Staudinger & Pasupathi, 2000).

Resilience appears to consist not least in flexibly coping with that which subjectively presents itself to us as “reality.” Even if we have the strong impression in everyday life that reality is outside of us and thus always undoubtedly present (and that it can be influenced by active behavior at most in the medium term—and then only to a limited extent), there is nevertheless no doubt that different individuals experience the same “reality” differently, in some cases *very* differently. This means there is a certain possible scope for “reality negotiation” (e.g., R. L. Higgins, 2002) for example, with regard to causal attributions or emotional evaluations, and which can be—and is—utilized functionally. This does not necessarily contradict the goal of authenticity (Harter, 2002; in as far as one regards this goal as indisputable; cf. above), it merely requires a person to not knowingly deceive others or put on an act (even though at times this can be a tough distinction).

Not least of all, it is important to find positive aspects even in negative developments (reframing). There are many indications that “benefit-finding” (Affleck & Tennen, 1996; Tennen & Affleck, 2002) or “meaning-making” (Nolen-Hoeksema & Davis, 2002; cf. also Baumeister & Vohs, 2002) are valuable resources against the negative consequences of stressful experiences or losses. However, it is by no means certain that these are mere constructions of the individual with a self-deceptive character (in the sense of “positive illusion”; Taylor & Brown, 1994). Rather, recognizing the often hidden but in fact real benefit of a challenging situation is actually an indication—almost a criterion—of self-related wisdom (Staudinger, Dörner, & Mickler, in press). Forms of reaction that reduce or even entirely avoid negative consequences by means of reevaluations and new perspectives on initially negative experiences (reframing) can be attributed to the “accommodative mode” (Brandtstädter & Renner, 1990, 1992) in Brandtstädter’s dual process model of development regulation (Brandtstädter & Rothermund, 2002).

If one regards development from a life span perspective, that is, as a permanent, dynamically changing subjective gain-loss ratio (e.g., P. B. Baltes, Staudinger, & Lindenberger, 1999; Staudinger & Bluck, 2001), it is clear that phenomena of resilience are by no means concentrated within certain life stages. Staudinger and Bluck (2001) have pointed out that traditional developmental psychology initially prioritized the study of childhood and (somewhat later) of adolescence, later supplementing this with an examination of old age from the mid-twentieth century onwards, but still largely ignored the long phase of middle adulthood. The argument developed there is that indeed midlife had not “caused any trouble” and therefore there was less need for investigating this life period. However, it is also argued that this lack of trouble is actually linked to the adaptive capacity of midlife rather than to a lack of stressors and crises (Staudinger & Bluck, 2001). And indeed middle adulthood is characterized by numerous crises. When parents die, children leave home, and the years left to work and live are steadily decreasing (Kim & Moen, 2001), this generates more acute awareness of one’s own finitude (cf. also Carstensen, Isaacowitz, & Charles, 1999), as well as the insight that many life goals may well remain unfulfilled forever and that “developmental deadlines” (Heckhausen, Wrosch, & Fleeson, 2001) may already have passed. Nevertheless on average no “midlife crisis” has been deserved. Thus, most likely the stressors are buffered by a rich set of resources and a resilience constellation occurs (Staudinger & Bluck, 2001).

Interestingly, also discussions of developmental psychopathology have traditionally (and, to a large degree, until recently) centered on childhood and adolescence. From the arguments presented up to this point follows, however, that successful (“healthy”) as well as maladaptive (“pathological”) development can and will occur throughout the life span. Thus, developmental psychopathology must not stay restricted to certain (early) stages of life, but rather broaden its perspective to also encompass middle and later adulthood. By doing so, additional options for interventions can be explored and potential structural equivalencies among developmental processes in childhood and old age may be discovered.

If our argument is correct that resilience designates a complex developmental dynamic whose effectiveness consists in avoiding clear phenotypic changes (Brandtstädter & Greve, 1994b; Greve, 2005), then middle to late adulthood would be the exact prototype for virulent, dynamic, and highly complex development, taking place to a certain extent “behind the scenes.” We may only notice these developmental resilient processes as such again in later adulthood because we tend to expect developmental losses, processes of disintegration and decline, and seek explanations for why these fail to occur (e.g., in the case of the “well-being paradox”; Staudinger, 2000).

With the action-related concept of development in mind, we must point out that resilience not only is reaction but frequently “proaction,” before the negative event or the degenerative development actually takes place. Findings on older people’s allegedly “paradoxical” fear of crime provide an interesting example of this phenomenon (Greve, 1998, 2000b). The common stereotype that older people are considerably more afraid of crime than younger age groups, although objectively the justification for this fear decreases with age, makes it clear that many discussions must be revised in the light of the conception of resilience. A closer look shows that this pattern of findings—frequently interpreted as an indication of “irrationality of old age”—is based on a simultaneously adaptive and highly functional behavioral tendency, which can be interpreted, in the light of the considerations presented in this chapter, as an expression of a proactive resilience. According to replicated findings, older people are *not* more frequently or more intensely afraid of criminality than younger age groups, nor do they consider themselves more likely to fall victim to criminal actions. Old people behave more cautiously than younger people, with the desired—and from this point of view not at all “paradoxical”—effect of a decreasing probability of victimization (Greve, 1998). The explanation as to *why* caution increases with age is complex

(Greve, 2004). One important aspect may well be the increasing—and also subjectively registered—biological vulnerability of older people, along with the consideration that *intentionally* cautious behavior in particular is determined by expectation-value calculations, which weigh the expected gain from risk behavior (“walking alone outside at night”) against the possible costs (falling and physical injuries in the event of attack) and make cautious behavior appear the more appropriate (“rational”) choice. A decreasing victim rate among older people over a period of several years can be described as an expression and consequence of a resilience constellation.

In the wider context of the arguments outlined here, it becomes particularly clear that it is inappropriate from our point of view to understand resilience as a state or even just a process (and certainly not as a trait). It is probably more appropriate to conceptualize the term resilience as a constellation of risk factors on the one and developmental outcomes on the other hand that is held together by resources encompassing regulatory processes as well as structural characteristics (Figure 21.1). We will return to two theoretical conceptions that describe the orchestrated interaction of this constellation through intrapersonal processes in more detail at a later point.

The phenomenon of resilience in late adulthood and old age can be examined and demonstrated in very varied psychosocial domains of functioning. For example, Staudinger, Marsiske, et al. (1995) have examined the domain of cognitive functions, and social relations and interactions in particular, in greater detail (cf. also P. B. Baltes, Lindenberger, & Staudinger, 1998; P. B. Baltes, Staudinger, & Lindenberger, 1999; Staudinger & Greve, 2001). However, the domain of self and personality is of crucial and indeed exceptional importance for the study of resilience in adulthood in two main respects. First, the plasticity and adaptivity observed in this domain offers a vivid and prototypical example for the resilience of adult individuals. Second, the adult self has an “orchestrating” function for human development in general and for resilient processes in particular (P. B. Baltes, 1997; see also Staudinger et al., 1995). We therefore focus on examples from the domain of self and personality in the following discussion, particularly because the theoretical approaches to be examined here have been studied extensively in this context.

The Resilient Self: Stabilization, Defense, and Adaptation of the Aging Self

A large number of national and international studies show that the functionality and overall positive status of self

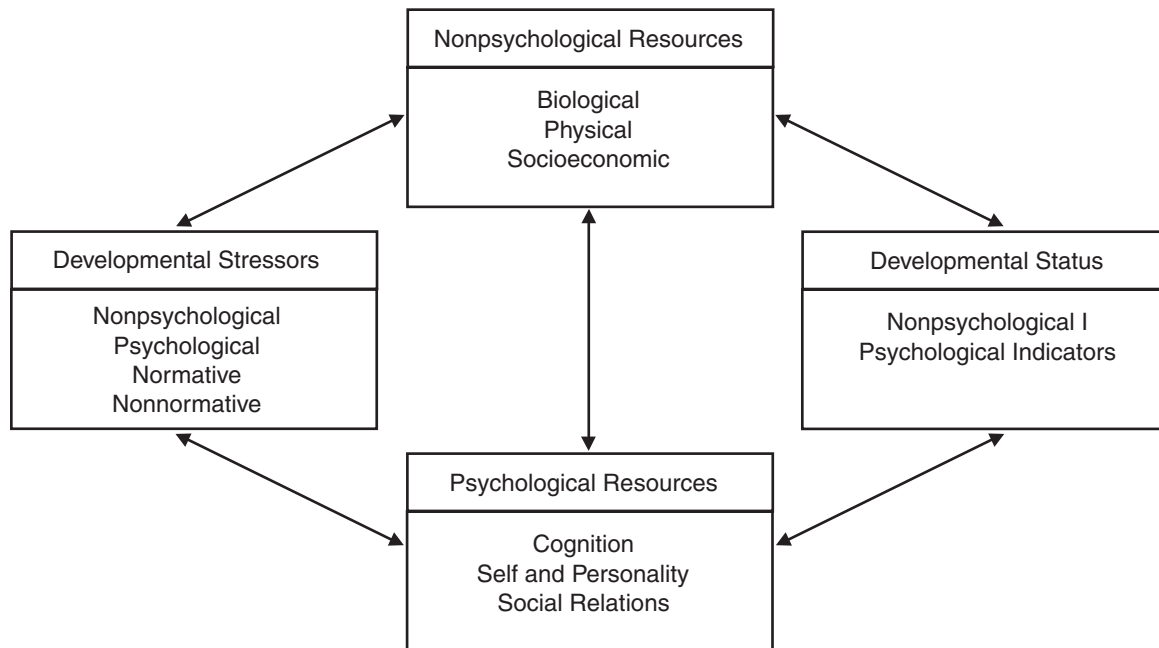

Figure 21.1 A model of resilience as a constellation of personal and contextual resources.

and personality generally diminish little if at all in old age (e.g., Greve, 2005; Roberts & Caspi, 2003; Smith & Baltes, 1996; Staudinger, 2000a; Staudinger, Freund, Linden, & Maas, 1999). Indicators for state of mind such as self-esteem (Bengtson, Reedy, & Gordon, 1985; Brandstädter et al., 1993), general well-being (Ryff, 1995), contentment with one's own age (Staudinger et al., 1999), and the conviction of being able to directly or indirectly control one's own life (M. M. Baltes, 1995; Brandstädter & Rothermund, 1994) show little to no change with age. This has made an essential contribution to rejecting, as too partial and incomplete, the stereotype of aging characterized by deficits and losses. This picture has been replaced by the more multifaceted image of "productive" aging, which emphasizes the opportunities and options of "successful aging" alongside the undisputed crises and losses (M. M. Baltes & Montada, 1996; P. B. Baltes & Baltes, 1990; Bond, Cutler, & Grams, 1995).

The aforementioned (cumulative) stability of the adult personality has, however, only at first glance been demonstrated clearly; as discussed earlier, genetic explanations in particular by no means suffice. Moreover, various approaches closely connect the concept of personality with that of the self ("personality as integrated self-system"; Bandura, 1999, p. 187; see summary in Greve, 2005).

However, if self and personality are not an endogenous component of the human psyche, their stability requires far more explanation than their variability, particularly in view of the plasticity repeatedly referred to earlier.

This finding of plasticity seems particularly astonishing in light of the well-documented fact that development-related processes of decline and functional setbacks emerge in many life and functional domains beginning in midlife. In fact, not only common stereotypes but also a large number of findings suggest that adverse situations begin to accumulate in later adulthood: Physical and mental performance declines, as demonstrated earlier, serious illness and disabilities are more likely to occur than in younger years, number of remaining years to live decreases, career orientations are lost due to retirement, close friends and relatives die. In relation to cognitive development (e.g., Reischies & Lindenberger, 1996), changes in sensory functions (Tesch-Römer & Wahl, 1996), and morbidity (e.g., Steinhagen-Thiessen & Borchelt, 1996), old age is characterized by an increase in factual losses and setbacks (for a summary, see, e.g., P. B. Baltes, Lindenberger, et al., 1998; P. B. Baltes, Mittelstraß, & Staudinger, 1994; P. B. Baltes, Staudinger, et al., 1999; Bond et al., 1995). This continually deteriorating balance of developmental gains and losses is apparently also perceived as such by the aging individuals themselves (Heckhausen,

Dixon, & Baltes, 1989). Moreover, the very subjective representation and evaluation of one's own person, that is, "the self,"⁵ would lose its function for behavioral regulation and control if it did not integrate the individual's objective developmental changes. For example, it is a necessary precondition for successful behavior to assess one's own competences and resources sufficiently realistically. The self does not have to be as veridical as possible, but as adequate as necessary if an increasing dysfunction with age is to be avoided (Greve & Wentura, 2003; see also the concept of "optimal margin of illusion"; Baumeister, 1989).

Old age is certainly a very rough indicator of the increase of risks, stresses, and losses (Staudinger & Fleeson, 1996). In fact, here one should not only separate different aspects (physical, cognitive, psychological, social, etc.) that develop in very different (sometimes even complementary) ways, but also take into account marked interindividual and situational differences that lead to an increasing heterogeneity of actual and chronic stresses in and throughout old age. In this respect, the success of coping is always relative; that is, it depends on the dimension under examination and the success criterion chosen (e.g., Filipp & Klauer, 1991).

Nevertheless, it is precisely the seeming contradiction between stresses and losses that increase with age, on the one hand, and the phenotypic stability of self and well-being of the aging person, on the other hand, that makes the processes and conditions of this constellation of resilience in old age such a fascinating research issue (Brandtstädter, 1999b; Brandtstädter & Greve, 1994a). The "discovery" of this apparent paradox is also due, however, to a negatively biased view of aging that also expects a failure in coping. In other words, it is the late effect of a deficit-oriented image of development in later life (Ryff et al., 1998).

The experience of the "coherence of personality" (Cervone & Shoda, 1999a) is due to a number of phenomena such as the observable convergence of human behavior even

across different contexts, but not least it is also due to the subjective (phenomenal) constancy referred to in the experience of the self that makes my biography *my* biography (Brandtstädter & Greve, 1994a; Cervone & Shoda, 1999b). Indeed, personality can really be understood as an integrated self-system (Bandura, 1999): the unity of behavior and personal identity. Human beings present and shape themselves and their environment through their behavior. Continuity is thus actively and sometimes also intentionally produced (Bandura, 1999; Brandtstädter, 1998, 2001; Greve et al., 2005). We produce stability by observing and checking ourselves (Roberts & Caspi, 2002). Hence, on the one hand, it becomes clear that the development of the self is the key to the question of development of the personality. At the same time, this also makes it clear that the combination of the themes "self and personality" is more than just two facets of the same domain that complement and supplement each other. Instead, this combination of perspectives may in fact be regarded as specifying the combination of genotypic and phenotypic perspectives on lasting behavioral tendencies; the *visible* stability and continuity of the behavior ("phenotypic personality") may be explained by the structural and motivational process continuity of the self in the interaction with variable situations and correspondingly specific cognitions and evaluations. Hence, our argument is that the apparent paradox of stability of the self-image and well-being in the event of permanent internal and external changes disappears if the personal constellation of resilience is moved into the focal point of the theoretical perspective (Brandtstädter, 1999b; Brandtstädter & Greve, 1994a; Staudinger, in press). Surprisingly, the application of the concept of resilience to explain the stability of self and personality in later life was attempted only relatively late (Ryff et al., 1998, p. 71; see also Staudinger et al., 1995). This is all the more astonishing as resilience apparently seems to be the rule rather than the exception (e.g., Brandtstädter & Wentura, 1995; Staudinger, 2000b).

Personality Traits as Elements of Constellations of Resilience

One aspect of resilience in the domain of self and personality is the search for personality factors that contribute to constellations of resilience, that is, that promote adaptive processes. (We have already pointed out that we do not follow approaches that view resilience itself as a personality attribute.) Thus, for example, findings from the Berlin Aging Study show that emotional instability, that is, neuroticism, moderates the correlation between physical risks and well-being (Staudinger et al., 1999). The authors argue

⁵In the context of this discussion, we have chosen not to go into more detail on the various conceptualizations of the self (see Leary & Tangney, 2003). In relation to the *contents* of the self, scholars generally distinguish between a cognitive-descriptive and an evaluative-judgmental (emotional) perspective. Both are highly multilayered and differentiated (e.g., in relation to affective, cognitive, and conative components). The *processes* of the self can be roughly divided into two functional categories: First, it processes self-relevant information in such a way that the individual capacity for life and action is retained or improved; second, it attempts at the same time to maintain as high a level of self-evaluation as possible (Greve, 2000a).

that it is precisely the intense experience of—also negative—feelings in the face of intense stressors that can have an adaptive effect, especially under conditions of lack of control. This is consistent with the discovery that under conditions of socioeconomic stress, the experience of negative emotions is more protective than a “surplus” of positive emotions (Staudinger et al., 1999). Other lasting aspects of personality (see Staudinger & Pasupathi, 2000, for an overview) that have proven to be at work in constellations of resilience are conscientiousness, openness to new experiences (Costa & McCrae, 1985), and self-efficacy (Bandura, 1986).

Self-Regulatory Processes as Part of Constellations of Resilience

It is no coincidence that the research on coping has paid so little attention to the concept of resilience for so long. Individual reactions to sources of stress and crises are typically made a topic of research only when they become apparent, or at least when sufficient cause arises to expect such reactions. The concept of “critical life events” (Filipp, 1995) illustrates this perspective aptly. The obvious link to clinical questions (Posttraumatic Stress Disorder or issues from the theory of depression) has lent additional support to the tendency to concentrate on phenotypic processes of change. This largely loses sight of the fact that, in many constellations of resilience, “active,” observable “coping” with “objective” sources of stress does not appear to occur at all.

When dealing with the subject of coping processes, one must keep several potential misunderstandings in mind. First, it should be pointed out that we are proceeding from a neutral conception of coping that includes both problem-oriented and emotion-centered coping forms (Lazarus & Folkman, 1984) in reaction to sources of stress and crises that, from a subjective perspective, exceed the individual’s currently and potentially available personal and social resources (Lazarus, 1991). This also includes what is known as “regressive” behavior (e.g., “relinquishing responsibility”; Haan, 1977). Both problem-oriented and emotion-centered forms of reaction presuppose an awareness or anticipation of a relevant cause, challenge, stress, threat, loss, or crisis: only perceived stresses must (and can) be coped with. Second, as mentioned earlier, in this sense, coping processes are not to be understood as antecedents or causes of resilience, but as elements of a constellation of resilience (see Figure 21.1). We argue, as explained earlier, in favor of a conception that identifies constellations of resilience—precisely in old age—as ways of dealing successfully with threatening and stressful life events and cir-

cumstances such that the former status and/or functionality of the relevant domains is restored or maintained. These conceptions raise the question as to what specific forms of reaction (under which personal and situational conditions) allow, for example, subjective well-being to be maintained or increase the probability of survival and thus contribute to a constellation of resilience.

In principle, as already addressed, it is possible to distinguish here between reactions in two different directions. First, losses and deficits that are impending or have already occurred may be confronted in a wide variety of active or assimilative ways (Brandtstädter & Greve, 1994a). Here, in other words, an attempt is made to change something about the menacing or critical situation, which is also possible even when the individual no longer has full control over this domain of reality. The active delegation of control may be another promising coping option: By delegating to others high-effort tasks that can no longer be carried out by oneself, while still maintaining control of localization, scope, and quality in the process, older people exercise a form of “proxy control” (M. M. Baltes, 1995). Proxy control can solve the problem without necessitating specific individual adjustments. However, in all the earlier mentioned cases, these active forms of coping are characterized by adherence to the threatened standards, value, and goal orientations.

However, not every problem can be reduced by active problem solving. Nor can eventual failure or irreversible losses be compensated through delegation. As the studies mentioned at the beginning of this section show, even in these cases, potential emotional and psychological effects (e.g., despair, grief, hopelessness, or depression) can apparently be regulated or completely avoided in the majority of cases. It is characteristic of the forms of reaction discussed here that changes in the threatened life and functional domains are evaluated in such a way that the stress is reduced or completely resolved. Adjustments of the personal value and preference systems, reinterpretations of stressful problem situations, changes in perspective, and downward comparisons are typical examples of self-regulatory processes that contribute, to a certain extent, to a resolution of the stressful problem situation and thus reduce its adverse effect on well-being and life satisfaction. The end point of these “accommodative” processes (Brandtstädter & Renner, 1990, 1992; Brandtstädter & Rothermund, 1995, 2002; see also P. B. Baltes & Freund, 2003) is that the individual has an altered view of his or her own person, goals, and situation in life. This, in contrast to defensive problem-avoidance reactions involving denial, actually makes the problem go away permanently; denying the existence of a sickness does

not cure it, but looking at it in relative terms makes it bearable. This is why we should not interpret denial and suppression as processes of resilience.

Assimilative and accommodative forms of coping are to be considered opposites to a certain degree. It appears that accommodative adaptation is primarily used if assimilative attempts to cope seem pointless. Conversely, premature adaptations of personal goals may unnecessarily hinder active attempts at problem solving. However, subjective goals are always integrated into a complex structure of value and goal hierarchies (Brandtstädter & Greve, 1994a). Goals defined at a lower level are simultaneously a means to achieve higher goals and values in the hierarchy. Thus, for instance, unrestricted physical mobility usually serves goals that, according to one's own personal definition of a good life and a life worth living, must be achieved or at least be achievable: traveling, walking, meeting friends, taking care of home and garden, and so on. In addition, physical mobility may (at least implicitly) be part of a positive self-image, a central component of which is not being dependent on the help of others. However, different goals and objectives are frequently incompatible simply because limited resources prevent them from being realized or maintained simultaneously (Brandtstädter & Wentura, 1995).

Self-Resilience: Content and Process

Bearing these findings in mind, the resilience of self and personality in old age, the starting point for our discussion in this section, now appears less paradoxical and more conclusive theoretically and empirically (see Staudinger, *in press*). Apparently, the (phenotypic) stability of the self in adulthood and old age is an indicator of resilience if the arguments in favor of change occurring throughout all of adulthood are taken seriously. This stability, however, may still seem surprising from a different point of view. Throughout a period of more than 50 years, experimental studies focusing on the processes of the self have frequently demonstrated a relatively high situational changeability of the self (e.g., Hannover, 1997; for a recent overview, see Leary & Tangney, 2003). Assuming that defensive processing of self-relevant information usually is not resilient, and that age-related decrements are recognized by the aging individual (Heckhausen, Dixon, & Baltes, 1989), how can the stability of the aging self be explained at all, let alone be conceptualized as a constitutive part of resilience in adulthood and age? The decisive point of our argument is that dealing with adversities (such as experienced losses or deficits) requires both a sufficiently realistic and, at the same time, a sufficiently stabilizing way

of processing. Several recent studies have successfully demonstrated that this task of reconciliation can be solved.

For instance, processes of "self-immunization" (Greve & Wentura, 2003) offer one way to continue maintaining aspects of the self-concept that constitute identity despite the admission of concrete individual changes and losses. Gutmann (1998) also uses the metaphor that the adult self is an immune system whose function is to safeguard integrity, identity, and well-being (self-esteem). Ryff et al. (1998, p. 77) use the term "immune competence." Self-immunization is achieved, for example, when a certain ability (e.g., remembering names or telephone numbers) has been acknowledged by the aging individual as lost or impaired, and the diagnostic value attributed to this ability with respect to the relevant higher domain (here, memory) is reduced and a comparatively higher value is attributed to other memory-relevant abilities (e.g., memorizing poems), which the person still believes he or she possesses. This is a further reason a multifaceted self-concept is advantageous. If the "good memory" aspect of the self-image is resting solely on memorizing telephone numbers, it is difficult to compensate by moving emphasis to other characteristics of a good memory (e.g., Freund & Smith, 1997). In addition to multifacetedness, research on the self-concept has demonstrated that the different facets need to be integrated and positively evaluated (Staudinger & Pasupathi, 2000).

A person's theory about himself or herself can also be immunized by restricting its range: The conviction "I have a good memory" is thus reinterpreted as "I have a better memory than other people my age," or even as "better than everyone else in my retirement home." This, too, is a peripheral concept adaptation that leaves the self-concept intact without disputing realities, such as that younger people do have a better memory than oneself (Greve & Wentura, 2003). Such processes explain how, through adulthood, people can apparently act in a very realistic and reality-oriented way and maintain a continuous and coherent self-concept despite even considerable change and development. Ryff (Ryff et al., 1998) refers in a similar context to the concept of (optimal) "allostasis," that is, of "stability through change" (Sterling & Eyer, 1988, p. 638; see also Staudinger & Pasupathi, 2000), which was originally conceptualized with regard to physiological stability (e.g., with regard to cardiovascular stresses and/or changes).

Analogous accommodative adaptations also manifest themselves with regard to the evaluative perspective of the self. Numerous studies have shown that a lower subjective significance is attributed to domains of functioning where losses have been experienced, and to compensate, aspects

of the self that appear to continue to be possible or available to a greater extent are given a higher value (e.g., Brandtstädter & Greve, 1994a; Kling, Ryff, & Essex, 1997). It is important to note that these adjustments do not deny realities (e.g., losses of abilities). Rather, they evaluate or interpret these (acknowledged) losses in a palliative or even neutralizing fashion. Precisely these accommodative dynamics of selection and compensation are the focus of the two models of developmental regulation in old age (P. B. Baltes & Baltes, 1990; Brandtstädter & Renner, 1990).

SUCCESSFUL AGING: A THEORETICAL FRAMEWORK

We have repeatedly pointed out that the stability of self and personality increases cumulatively over the life span (Caspi & Roberts, 1999; Roberts & Caspi, 2003). It is a widely held belief that in childhood and youth and up to early adulthood, change and transformation are not just normal, but indeed, are to be expected (the *absence* of observable short-term changes in children triggers astonishment and questions), whereas with adults, it tends instead to be dramatic change that requires explanation. The central thesis of this chapter is, however, that it is indeed the increasing stability and continuity in adulthood that is an expression of underlying change. The phenomenon of ordinary resilience in middle and later adulthood turns such changes into stability (Roberts & Caspi, 2003; Staudinger, in press). In particular, structures and processes of the self play a dual key role here (Greve et al., 2005). On the one hand, they actively contribute to the stabilization of behavior (the reaction of the person to his or her environment) by means of various mechanisms. On the other hand, as we mentioned, a central function of many processes of the self is to stabilize the self-perception precisely when objective conditions (of the environment as well as of one's own person) change; this in turn not only stabilizes self-presentation (in everyday behavior and also in questionnaires) but also produces the subjective continuity that makes it possible to be certain that one has remained the same person as before. In this sense, the self acts as the interface between the subjective and objective sides of the person and, at the same time, as the stabilizer of both sides. The development of the self in middle and later adulthood produces the internal and external impression of stability that has long been established through empirical research (Greve, 2000a).

Surprisingly, research in developmental psychology has only very recently focused attention on the resilience of the self in adulthood and later life and thus still lacks dif-

ferentiation in many respects. There are three main reasons for this late development. First, only recently has developmental psychology extended its perspective on the self and personality to encompass periods beyond childhood and adolescence, the latter of which was formerly a particularly strong focus. Although the dynamics of identity development throughout the entire life span were highlighted as early as Bühler (1933) and, from another perspective, Erikson (1959), research in developmental psychology on the self-concept has remained narrowly confined to those aspects of self-development in which processes of change are prominent or dominant, or at least easily recognizable. This applies in particular to the development of the self during youth and adolescence, when establishment of a differentiated and integrated, autonomous and socially competent identity may be seen as the central developmental task (for a summary, see Harter, 1998, 1999). The high stability of the self beyond adolescence has apparently been widely viewed as an indicator of the *lack* of developmental processes (for an exception see Freund & Smith, 1997).

Second, with regard to the period of later adulthood and old age, which is characterized by visible changes, gerontopsychology has long directed attention to other functional domains through a deficit-oriented model of age and aging. These domains include, at the individual level, primarily cognitive developmental processes and regressive processes of sensory and motor functioning, along with the social dynamics of "disengagement" (see Cummings & Henry, 1961). This point of view has defined psychological and physical health and/or stability as the absence of illness or stress (Ryff et al., 1998) rather than as a positive phenomenon (see also Aspinwall & Staudinger, 2003).

Third and above all, however, research on the self-concept and on coping, conducted to date primarily in social psychology, has investigated mainly *visible* changes or at least reactions to *obvious* causes for changes—insofar as *changes* in the self beyond childhood and youth were dealt with at all. From this perspective, the high diachronic intraindividual stability of the self in middle and later adulthood up to old age (see Pinquart, 1998) has been taken to indicate, if anything, the fact that coping resources are being utilized well. This in turn produced the conclusion that the self does not develop in later adulthood or old age (Greve, 2000a).

A Theoretical Framework for Research on Resilience in Middle and Late Adulthood

In this chapter, we have referred at various points to the model of selective optimization with compensation (P. B.

Baltes & Baltes, 1990; P. B. Baltes & Freund, 2003; Freund, Li, & Baltes, 1999; Freund & Riedinger, 2003) and to the dual process model of development regulation (Brandtstädter & Rothermund, 2002). It is evident that both take the phenomenon of resilience in adulthood and later life as a starting point (this term is also used in P. B. Baltes, 1997; Brandtstädter, 1999b; Staudinger et al., 1995). We argue in favor of the idea that not only do these two models deal with the same phenomena, but they can also be directly connected.

As already indicated, in the face of irreversible setbacks and losses (e.g., partner's death, chronic illness, progressive processes of decline), accommodative reactions that do not attempt to actively solve the problem but to counteract the resultant stress become increasingly promising and probable with advancing age (Brandtstädter & Renner, 1990), and assimilative strategies decrease in importance (Brandtstädter, 1992). For both assimilative and accommodative reactions, it is possible to differentiate among selective, optimizing, and compensatory processes. As far as selection is concerned, it is a question of choosing between alternatives and setting limits. However, selection alone is not sufficient; what is also required is a commitment to achieve the desired condition—in other words, optimization. This may be done by improving the means available or by finding other, more optimal contexts. Finally, if the endeavors are met with obstacles, the option of switching to other paths to achieve the goal is required—in other words, compensation. Compensation becomes necessary if the means originally used are no longer available or have lost their effectiveness. The following example aims to illustrate how the two development regulation models can be combined.

Assume that I am no longer able to climb the stairs to the fourth floor. I can, for example, rent an apartment on the first floor (assimilative selection). If I place a lower value on my physical abilities and a higher value on my education (accommodative selection) in my own self-evaluation, I do not feel any worse about myself as a result. If I would like to stay in the fourth-floor apartment, I could have a chair lift installed (assimilative compensation). Furthermore, I can maintain my self-concept—the idea that I possess good physical abilities—by changing the person or group I compare myself with in self-evaluation in order to appear more competent by comparison (accommodative compensation). Finally, I can engage in assimilative optimization by buying myself the best chair lift available and practicing how to use it. Alternatively, I can engage in accommodative optimiza-

tion by having a wide choice of reference groups available that produce the same result.

Even with an increase of irreversible losses and deficits, coping episodes in later adulthood and old age can usually be reconstructed as interlocking combinations of complementary assimilative and accommodative processes, as the two directions of coping can point toward different goals. Not least, modifying personal goal structures and preferences can also recreate the ability to control highly valued goals and thereby also (subjectively) enable active efforts that previously appeared to be pointless and would have taken up valuable resources unnecessarily (Brandtstädter & Rothermund, 1994). And indeed this is what we find when studying the distribution of psychological energy across central life domains, that is, personal life investment (e.g., Staudinger et al., 1999), across different ages. Developmental tasks of different ages are reflected in the respective investment profiles. The domain's friends receive highest investment priority in adolescence, profession and friends rank high in young adulthood, profession and family rank high in middle adulthood, and health and family rank high in old age.

These phenomena are a central function of the aforementioned selection processes (P. B. Baltes & Baltes, 1990). The reduction of aspiration levels can be similarly classified. Being permanently unable to fulfill a specific criterion of physical fitness—for example, climbing several flights of stairs with ease—due to aging motivates accommodative coping. This may, however, lead to a more age-appropriate definition of physical fitness that can then be actively pursued. Equally, compensation processes call for active *and* accommodative regulations. If otherwise effective repertoires of action fail to achieve goals or maintain standards, the individual seeks alternative paths of action, possibly involving compensatory aids (e.g., a hearing aid). The precondition for this step, however, is an acceptance of irreversible losses on a subordinate goal level: Only individuals who can cope with a self-definition of being hard of hearing, and thus accept a hearing aid, can maintain (relatively) effortless communication (Tesch-Römer, 1997).

Coping may also be preventive, that is, take place before the stressful event or the degenerative development occurs (compare the concept of anticipatory coping in Aspinwall & Taylor, 1997). One interesting example of this phenomenon is provided by the aforementioned findings on older people's allegedly paradoxical fear of crime interpreted in the light of our conception of resilience. The fact that our knowledge compensates for losses in the mechanics of our

mind (P. B. Baltes, Lindenberger, et al., 1998) may also be viewed as anticipatory coping. However, in this case, coping is not an intentional but an automatic process.

A Life Span View on Resilience as a Helpful Framework for the Study of Developmental Psychopathology

Throughout this chapter, we have argued in favor of a life span perspective on development in general and on processes of resilience in particular. If these arguments hold, the study of developmental psychopathology also has to be viewed as a life span science. Without doubt, it is important to further investigate processes of resilience (and vulnerability) among children and adolescents (Luthar, 2003), particularly to learn as much as possible about means of early prevention and intervention. However, it might be not only too narrow, but even misleading to restrict research in developmental psychopathology to these earlier phases of the life span. The acknowledgment of processes of maladaptation and pathology throughout the life span surely will help to properly understand the basic nature and dynamic of these processes. The study of psychopathology and resilience shares a number of characteristics—one may even argue that they are two sides of one coin—that support this proposal.

First, the identification of developmental psychopathology as well as of resilience asks for an evaluative judgment. Moreover, both concepts refer to the very same normative points, namely, the “normality” (or even successfulness) of a certain course of development (which is maintained in cases of resilience and lost in cases of maladaptation or pathology). As a consequence, both developmental psychopathology and research programs focusing on resilience share the common need for a normative theory of development.

Second, the research on resilience has demonstrated that development occurs even in cases in which stability or at least no dramatic changes are observed. This refocuses attention on the dynamics going on behind the scenes, a perspective that may also prove useful (or even necessary) for research on developmental pathology. Irrespective of whether a certain developmental state (say, a certain degree of grief) is labeled maladaptive, the crucial question may be not to declare an arbitrary cutoff value for a phenotypic phenomenon (be it stable or varying), but rather to identify the adaptivity or maladaptivity of the processes producing this developmental phenotype. This refocusing may further help to identify more general patterns and processes of (successful or maladaptive) development.

Third, please recall that the life span notion of resilience suggested in this chapter encompasses maintenance and recovery as well as loss management as three important facets. To make loss management a part of resilience calls attention to the relativity of what is called resilient and what is called pathological. A resilience constellation in the sense of loss management may actually result in levels of functioning that are below normal. But given the stressors and threats under which the individual is operating, this level of functioning is still to be called resilient rather than pathological. By the same token, sometimes maintaining “only” normal levels of functioning may not be called resilient because extant stressors could be dealt with more successfully. In other words, the focus on resilience in old age can help to identify cases of developmental pathology that, at first glance, seemed to be cases of stability (and, at the same time, declare other cases as nonpathological that seemed to be maladaptive).

Finally, taking a life span perspective on developmental psychopathology asks for taking into consideration a diachronous as well as a synchronous effect of a given constellation. That is, a certain developmental path in early childhood may be the root of a successful course of later development even if, at a first synchronous glance, it seems to be a maladaptive constellation or vice versa. For example, the mother of a blind child who refuses to allow the child to move through the house may be the cause of synchronous desperation on behalf of the child, but also of assimilative efforts of the child to use other senses to gain orientation. In turn, a concurrently successful developmental constellation, such as the big success of a child in sports, may in the long run have dysfunctional effects, such as a heart condition or hurting joints.

RESILIENCE IN LATER ADULTHOOD AND OLD AGE: PERSPECTIVES FOR RESEARCH AND INTERVENTION

Resilience, like vulnerability and adaptivity, entails a normative facet as a constitutive part. It means more than simply stability (or continuity or unchangeability), but rather the capability to resist (potentially) harmful influences, circumstances, or experiences. Whether or not a given event is harmful (etc.) cannot be decided without referring to a normative standard. With respect to subjective well-being, this observation often seems trivial: If a person feels sad or depressed, if he or she suffers from the symptoms or consequences of a disease or decrease of capacities

(e.g., deterioration of hearing and sight) or has experienced serious losses (e.g., death of partner), it seems obvious that a reduction of well-being is the result by default. However, even in these cases, it is less obvious what period of grief or sadness, what amount or degree of depression or pain is normal or appropriate, and at what point it might be described as “too much.” Moreover, in many other cases, and with respect to most other possible indicators of a critical event, it is often just the reaction itself that indicates that an event has been “critical.” Only if a person shows depressive symptoms over a long period after a separation is it called a critical life event. Otherwise, it may be viewed as a relief or a challenge.

Human development is characterized by a considerable plasticity (e.g., P. B. Baltes, Staudinger, et al., 1999; Lerner, 1984), which not only forms the central prerequisite for the resilience processes mentioned, but is generally a precondition for lifelong development. Processes of self-regulation are not only a central criterion of this adaptation process, but also steer it to a large extent. Subjective well-being and psychological health can be preserved or improved only if resilient constellations of resources protect the person against unfavorable conditions, if personal and social coping resources help to offset and compensate the—inexorable—occurrence of crises and losses, and if individual competence is preserved in large part, whether by stabilizing the respective prerequisites or reorienting efforts toward attainable goals. Development consists, if these arguments hold, essentially in the maintenance and implementation of the individual’s ability to adapt to discrepant situations (developmental tasks) by seeking, either through assimilation or accommodation, to (dis)solve the critical and stressful discrepancy in cases where the situation cannot be avoided permanently. Optimal, successful development implies *progressive* adaptation, which preserves or increases this plasticity and adaptivity as much as possible. This leads to the apparently paradoxical statement that development can be described as *successful* when it (i.e., progressive adaptation) can take place at any given time, and in fact does.

Successes and failures are constitutive for actions and histories of action and make up the dramaturgy of life; essential aspects of our activities in life consist in coming to terms with unanticipated and undesired effects of earlier actions and decisions. This also has consequences for theoretical questions of optimal development and successful aging. The unfortunate choice of either electing specific values and goals (authenticity, control) as criteria for successful development or forgoing judgments of success or failure altogether, can be avoided if metacompetencies are

included as criteria that enable the person’s further development and adaptation (P. B. Baltes & Baltes, 1990; Brandtstädter & Schneewind, 1977; Greve, 2001; Staudinger, 1999b). Beyond merely demanding that vital basic needs are met, successful development and successful aging call for competencies and resources that can compensate for deficits and vulnerabilities and help us successfully achieve personal goals, while taking into consideration basic conditions for sensible coexistence. From this perspective, the abilities to select developmental goals, make competent decisions, actually realize them and thus overcome resistance, as well as to review goals and strategies in the light of new experiences are all essential aspects of successful development (see Bandura, 1989; Brandtstädter & Lerner, 1999). The basis for successful development appears to be that competencies are built up and perfected, and thus that opportunities for further development are sustained and expanded.

In this context, the Janus-faced function of goals should not be overlooked. On the one hand, goals give life meaning and coherence. Having goals is indeed itself an indicator of life satisfaction (see Brunstein, 1993). On the other hand, goals become sources of dissatisfaction and frustration if they are not—or no longer—attainable. Goal importance and goal commitment moderate the relevant effects; a strong *commitment* intensifies positive feelings in the event of success but also intensifies negative feelings in the event of failure. Precisely for this reason, the attempt to theoretically define optimal development and successful aging in terms of the successful pursuit of goals is inadequate. As explained earlier, individual action takes place in life situations and developmental contexts that are sometimes non-transparent and controllable only to a certain extent. A more comprehensive theoretical explanation of optimal development and successful aging hence also requires taking into consideration the processes and resources that make it possible for a person to cope with irreversible losses, to detach himself or herself from unattainable goals or life projects, and to flexibly balance personal goals with available options of action (Brandtstädter, 1998).

Despite the relatively short period in which the concept of resilience has been dealt with in the context of later adulthood and old age, the research has produced substantive and differentiated results (i.e., the phenomenon has been investigated thoroughly, although the term resilience itself is not always used, or in any case, not in the sense described here). The surprisingly high (in view of widespread aging stereotypes) psychosocial robustness and plasticity of the aging person and of his or her personality and identity, which can also be found in many different domains of

functioning, have come to the fore of research interest. The life span perspective additionally calls attention to the limits of resilience and plasticity and the increasing dependence on external resources in later life.

What is crucially needed at this stage, apart from the replication and differentiation of many findings referred to here, is a comprehensive theoretical framework for psychogerontological resilience research. This framework would not only overcome the conceptual heterogeneity mentioned earlier and lamented repeatedly in the literature (Luthar et al., 2000; Masten, 2001), but would in particular integrate the various approaches—from life span developmental psychology, gerontopsychology, and research on self-concept and coping—that all help to explain the phenomenon of resilience. In addition to the models of selective optimization with compensation (P. B. Baltes & Baltes, 1990; P. B. Baltes & Freund, 2003; Freund et al., 1999) and the dual process model of developmental regulation (Brandtstädter, 1998; Brandtstädter & Rothermund, 2002), other approaches worth mentioning here are the model of primary and secondary (development) control (Heckhausen & Schulz, 1995; Rothbaum, Weisz, & Snyder, 1982), the distinction between problem-centered and emotion-centered coping (Lazarus, 1991), and social-psychological research into the “dynamic” self (Leary & Tangney, 2003; Markus & Wurf, 1987). The theoretical framework to be established should, at the same time, be theoretically and empirically linked with the subpersonal level (e.g., cognitive psychology) and the transpersonal level of macrosocial approaches (e.g., social risk factors). In particular with respect to the former aspect, it is crucial to focus more on the “biological contributors to resilience” (Curtis & Cicchetti, 2003). In a recent review, Curtis and Cicchetti have convincingly argued that research on resilience in the past 30 years or so has mainly focused on psychosocial correlates and conditions of resilience processes. They argue in favor of an expansion of the scope of the concept of resilience to include the biological level. At the same time, however, Curtis and Cicchetti demonstrate that a reduction of resilient processes to this level must be avoided for several reasons. Beside aspects of resilience such as equifinality and multifinality that are mentioned in their plea, we would add that the inherently normative basis of resilience makes it impossible to reduce this concept to a mere physiological (e.g., neural) level. Obviously, however, the proper explanation of processes of resilience entails basic physiological processes as well. Neural plasticity (Huttenlocher, 2002) is one of the central fundamentals for the mere possibility of resilience to occur.

Research on resilience will develop productively in the future only if unnecessarily confrontational stances (e.g., person-centered versus variable-centered approaches, nature versus nurture of resources of resilience) are set aside in favor of integrative approaches. It is increasingly important to better understand processes of resilience in their relational character. Gaining knowledge about the mediating processes, including their diachronic logic, is also of central significance, among other things because diverse research on self-regulation has shown that the adaptivity of self-regulation resources depends largely on when during the regulation process it is implemented (e.g., Staudinger, 1997). For instance, there is indication that realism promotes adaptation in the phase of setting a goal, but optimism promotes adaptation more in the phase of implementing a goal (Taylor & Gollwitzer, 1995). Similarly, research on coping shows that spending time in deep thought after a bereavement is functional in the first 6 months, but dysfunctional if it continues longer (e.g., Filipp & Klauer, 1991; Wortman & Silver, 2001). Therefore, whether something is a resource or a hindrance also depends on when the behavior or trait is implemented.

We have singled out in particular two theoretical approaches that appear most promising in this context and that have, in the past decade in particular, been responsible for great strides with regard to overall theoretical integration. However, more far-reaching efforts toward integration are both desirable and urgently needed. The conceptual differentiation outlined here among plasticity, resilience, and loss management is only one example in this context (e.g., Staudinger et al., 1995). A further pressing task would be to examine functional equivalents between the dynamics and processes discussed and adaptive aspects of psychomotor functioning and cognitive development in later adulthood and old age. The structural parallel between phylogenetic and ontogenetic development dynamics has also been widely ignored in the current theoretical discussion, and thus concepts of evolutionary biology have been used very little to develop theories of psychogerontology (see, however, P. B. Baltes, 1997).

This suggests that it would be most promising to extend empirical research on the concept of resilience in old age in the psychosocial domain beyond this domain as well. Scholars are already discussing physiological and particularly psychoneuroimmunological processes, particularly in the context of stress reactions and their consequences for mental and physical health (for a summary, see Curtis & Cicchetti, 2003; Ryff et al., 1998). However, countless other areas are conceivable and logical, precisely concerning the issue of predictors of optimal aging, for instance,

questions of motoric resilience (e.g., under which personal conditions do, for example, falls cause no harm?), communicative resilience (e.g., who seeks and finds a constructive way out, even in “unsuccessful” discussions, social “dead ends” and conflicts?), resilience in partner relationships (e.g., who maintains a positive and balanced relationship, even under stressful conditions, for example, in a caring context—“wife cares for husband”?), economic resilience (e.g., who can keep the components of a certain standard of living—healthy eating, leisure activities, social commitment—stable even under varying, particularly increasingly tight economic restrictions?).

Two further directions of research previously neglected in connection with resilience, but forming one focus of the life span perspective, appear very promising. The first is support of constellations of resilience. Particularly in old age, when external resources take on increasingly important functions, this form of resilience comes to the fore. At this point, we must emphasize once again that the domain of self and personality represents only one sector of the relevant components of constellations of resilience. For instance, the nonsocial, that is, physical and material, characteristics of the environment form a component of resilience in old age that cannot be overestimated (e.g., Lawton, 1989). We are only beginning to explore the intervention potential in the physical and material characteristics of the environment.

A second main desideratum is to conduct prospective longitudinal studies, which should also include data recorded before the onset of stress, if possible (e.g., Wortman & Silver, 2001). This could take the form of studies covering the entire life span (e.g., Robins et al., 1996) or of targeted samplings from risk groups (e.g., Bonanno, 2004; Fredrickson et al., 2003). These studies are extremely important because the interaction between stress factors and the protective resources that constitute the phenomenon of resilience has not yet been researched sufficiently (Masten & Coatsworth, 1995). Thus, adverse conditions on the one hand could (under certain conditions) erode the existing resources (and thus intensify the negative effect of stress on well-being and further development), but on the other hand also have a strengthening effect on the individual (Pellegrini, 1990; Rutter, 1985; see also Kobasa, 1979): They could challenge the individual to build and develop resources that at some point could diminish or completely neutralize the effect of this stressor.

A central objective for further research will have to be better understanding of the processes of adaptation. Since Barkow et al. (1992) established the discipline of evolutionary psychology with the publication of their pioneering

work *The Adapted Mind* (for a summary, see Buss, 2004; Gaulin & McBurney, 2004), it has become impermissible to use the concept in a purely metaphorical or summary sense. Indeed, research on resilience (and also on coping) might well benefit from a study of the functional equivalents between an evolutionary concept of adaptation and the intrapsychological adjustment to adverse conditions.

To put it another way, the goal of future research must be to bring together psychological and biological perspectives, not only combining the variables observed in each case (e.g., cognitions and emotions on the one hand and brain activity and hormones on the other), but also integrating them in a theoretical sense (Curtis & Cicchetti, 2003). On this point, Ryff and Singer (2002) refer to E. O. Wilson’s (1998) call to again begin striving for a unity of science, which he calls “consilience.” As we have seen here, resilience could help pave the way toward achieving this goal.

In the past decade, consensus has emerged that the stigma incurred by mental illness represents the most important issue facing the entire mental health field (Corrigan, 2004; Crisp, 2000; U.S. Department of Health and Human Services, 1999). Specifically, whereas the symptoms of mental disorders produce considerable impairment and suffering and often limit the attainment of developmental competencies, the extreme social disapproval of persons with mental illness greatly compounds these problems. For one thing, stigmatization precludes opportunities for treatment. Indeed, current estimates are that over three-fourths of children and adolescents with mental disorders in the United States never receive evaluation or treatment (New Freedom Commission on Mental Health, 2003), reflecting (1) ignorance that many behavioral and emotional prob-

lems reflect mental disorders, (2) shame on the part of families with respect to admitting that their offspring have a mental illness, and (3) a lack of adequate funding for treatment, even if it is sought (Hinshaw, 2005). In addition, stigma limits the potential for independent functioning; it also stands in the way of the kinds of research funding needed for advances in the struggle to overcome mental disorders (Sartorius, 1998). Thus, as highlighted by Link and Phelan (2001), stigma occurs at structural levels in society (laws, cultural norms, policies) and within individuals and families (stereotypes, beliefs, prejudicial attitudes). Self-stigmatization is also salient, to the extent that persons with mental disorders internalize the negative messages they receive (Corrigan, 2004). Overall, the devaluation of mental illness has effects that emanate across

individual and family lives, the well-being of communities, and the nature of the very enterprises of research and treatment efforts that could help to overcome the impairments related to mental disorder. Given the increasing recognition that mental illnesses are now among the most debilitating and impairing diseases that exist worldwide (Murray & Lopez, 1996), understanding the reasons for the shunning, exclusion, and punishment of persons with mental illness across history is an essential goal.

Developmental factors are crucial to the discussion. Indeed, because of the continuity and predictability of development across the life span (Rutter & Sroufe, 2000), stigma at a given phase of development is likely to have profound implications for future functioning. Furthermore, when parents suffer from mental illness, their own propensity to be stigmatized can have major effects on their children's development (Hinshaw, 2005). In short, the stigma related to mental disorder is ripe for developmental theorizing and developmentally oriented research efforts.

The outline of this chapter is as follows: I first define stigma and then discuss psychological, social, and evolutionary models and mechanisms related to stigmatization. I next consider historical themes related to stigma, particularly with respect to children with mental disorders, and weigh various types of evidence for stigma regarding mental disorder, including both empirical research and broader kinds of data from general cultural practices. After evaluating developmental issues and concerns, I present a model of stigmatization as it pertains to mental disorder across the life span. Finally, I review key research questions remaining to be addressed by future generations of investigators. Although overcoming stigma is a topic of vast importance, space limitations allow only a brief conclusion regarding the types of intervention strategies that may be most effective in reducing stigma (for more extensive coverage of such ideas and procedures, see Corrigan, 2005; Corrigan & Penn, 1999; Hinshaw, 2006).

DEFINING STIGMA AND STIGMATIZATION

Stigma is a term originating from ancient Greece signifying an actual mark or brand placed on or burned into the skin of members of castigated groups, such as slaves and traitors. The mark graphically signaled the devalued nature of its carrier (Goffman, 1963). In present usage, the mark is typically symbolic, referring to the social judgment placed on members of groups considered deviant or im-

moral, the discrimination they receive at the hands of the majority, and the psychological sense of shame and degradation likely to develop in those who are stigmatized.

Several key points are central to current notions of stigma. First, stigmatization exists as part of a series of interchanges, with a group carrying social power denigrating and castigating a group lower in power (Link & Phelan, 2001). Thus, what is stigmatized cannot be dissociated from social hierarchies and social orders. Note that because there is malleability in terms of what is considered proper and good in various cultures, this point gives some hope, in that if persons with mental illness become less disenfranchised, stigmatizing practices may diminish.

Second, stigma carries particularly stressful consequences if the stigmatized condition is potentially concealable—as is the case for many persons with histories of mental illness—because of ramifications that emanate from decisions about disclosing versus hiding the stigmatized attribute (Goffman, 1963; Jones et al., 1984). Unlike the overt nature of racial characteristics, the covert experience of mental disorder presents a host of choices that may yield considerable anxiety for both individuals and family members.

Third, stigmatization can be viewed as a set of social processes (comparison, castigation, “marking”) that lead to continuing denigration. One such process involves the nearly automatic social cognitions that are invoked when members of a society confront a member of the outgroup (Myers, 1998). Another is the tendency for global attribution of negative traits to the individual's “mark.” Still another includes the potential for self-fulfilling prophecies, whereby the expectation of deeply dysfunctional behavior and interaction may color and shape subsequent encounters with the individual. That is, with any imperfections automatically attributed to the flawed character of the entire person, the degraded individual's behavior may begin to conform to the initial stereotype (Jussim, Palumbo, Chatman, Madon, & Smith, 2000).

Fourth, although stigma shares elements with stereotyping (a cognitive process of viewing a subgroup in global terms), prejudice (an affective, negative prejudgment of members of a castigated group), and discrimination (the behavioral curtailing of rights of such a group), it transcends these constructs because of the strong tendency for perceivers to view all aspects of stigmatized individuals in terms of the fundamental flaw or deviance involved and for the castigated individual to internalize the aspersions that are made (Hinshaw, 2006). Thus, stigma processes are at once fascinating, complex, and pernicious.

At first glance, it would be logical to assume that stereotypes, prejudices, and discrimination are linked in expectable and predictable ways, such that stereotypes lead inevitably and automatically to prejudicial attitudes, which in turn predict and promote discriminatory practices and lead to stigmatization (for discussion of the fluid boundaries among cognitive, affective, and behavioral components of stigmatization, see Dovidio, Major, & Crocker, 2000). Yet, it is quite possible for an individual to voice stereotyped beliefs ("People with mental disorders are unpredictable") or prejudicial attitudes ("Such people are despicable and filthy") but also to maintain contact with certain persons with mental illnesses. Complicating matters further are the forces in modern society that tend to inhibit overt expression of prejudicial attitudes, so that many biases may exist at covert, implicit levels (Greenwald & Banaji, 1995). Finally, although the usual assumption is that stereotypes and prejudices predate and cause discriminatory practices, the causal arrow may be reversed: A history of discrimination against an outgroup can foster stereotyping and prejudice, with the prejudicial attitudes serving as "system justification" for the inequities that are the core of the problem (Biernat & Dovidio, 2000; Crocker, Major, & Steele, 1998). In other words, given the ubiquity of hierarchical divisions of power and resources in all societies, those at or near the top rung will engage in denigration and derogation of less enfranchised members of the hierarchy to fuel the perspective that their higher status is justified and fair. Such "legitimizing myths" (e.g., the belief in a merit-based society or in a world that is fundamentally impartial and fair) serve to bolster the status quo and ease the minds of high-status perceivers, such that their privileged status appears to be the result of effort and sacrifice rather than emanating from an enforced, discriminatory system (Pratto, Sidanius, Stalworth, & Malle, 1994). This point exemplifies a theme that runs through the entire chapter, namely, that stigmatization is located simultaneously in psychological processes, such as social cognitions; social interchanges, including those at dyadic and large-group levels; and cultural practices and policies, involving structural inequalities and legislative mandates.

A key underpinning of stigmatization was perceptively noted by Goffman (1963): The globalized, negative nature of stigma means that perceivers often come to believe that the marked person is less than human. When such an ascription is made, harsh punishment, exploitation, and even annihilation are not far behind (Sternberg, 2004). Later in the chapter I address the crucial issue, in terms of mental illness, of the kinds of causal theories that may lead to per-

ceptions of the fundamental humanity versus subhumanity of individuals with extremes of behavioral deviance.

Does stigma always portend negative self-image for members of stigmatized groups? Although this was formerly held to be the case (Allport, 1954), it is now well-known that many stigmatized individuals, particularly those in ethnic or racial minorities, have self-esteem that is quite high (e.g., Crocker & Major, 1989). Hence, although stigmatization is likely to lead to shame in many instances, lowered self-image is not inevitable. In the case of mental illness, however, the symptoms of many disorders include dysphoria and low self-esteem; when these are coupled with the moral outrage and blame often voiced by social perceivers, decreases in self-worth would be quite predictable. The reality is that individual differences in response to stigma are vast, and understanding these varied reactions and coping strategies is a major goal for future research efforts (Corrigan & Watson, 2002).

Finally, is stigma universal or culturally specific? Increasing attention is being paid to the universal aspects of stigmatization, which may betray an evolutionary basis for at least some aspects of social exclusion (Kurzban & Leary, 2001). Indeed, mental illness has received consistent castigation and stigmatization across history, leading to speculation as to the ingrained roots of fundamental social tendencies to exclude persons with extreme behavioral deviance—with the clear implication that efforts to overcome the stigma of mental illness will need to be hard-fought. On the other hand, traits or conditions that are stigmatized in one culture or one historical era may come to be valued in others; for example, note the fluctuating ideals of women's body size in different nations and periods. Thus, there is hope that increased tolerance for diversity of behavior will help to erode the stigmatization received by persons with mental illness in the future.

THEORETICAL PERSPECTIVES ON STIGMA

Stigma is a vibrant topic in current research on social psychology, intergroup relations, and evolutionary psychology. Although most research on stigma has focused on racial and ethnic minority groups, a host of conditions are stigmatized in current society: gay/lesbian status, adoption, receipt of welfare, old age, and left-handedness, to name just several among a long list. As I discuss subsequently, mental illness is one of the most stigmatized attributes or traits that a person can have (Hinshaw, 2006; Tringo,

1970). My purpose in this section is to lay out some of the core themes from social and evolutionary psychology perspectives on stigma and comment on their applicability to mental disorder. The research on stigma in recent years has been voluminous; see other sources for a more comprehensive account (e.g., Crocker et al., 1998; Gaertner & Dovidio, 2000; Heatherton, Kleck, Hebl, & Hull, 2000; Hinshaw, 2006; Major & O'Brien, 2005).

Social Psychology and Stigma

Fifty years ago, most accounts from a psychological perspective were based on the proposition that prejudice and stigma stem from deep-seated, individual-difference proclivities (such as authoritarian personality styles) that predispose an individual to bias and hatred (e.g., Adorno, Frankel-Brunswick, Levinson, & Sanford, 1950). Currently, the social psychological view has shifted to emphasize the universality of social comparisons, the ubiquity of stigmatization processes, and the embeddedness of stigma in normal psychological functions and processes (e.g., Dovidio et al., 2000). In other words, social comparisons, even those that are sufficiently negative and harsh to earn the name "stigmatization," emanate from common and pervasive social and developmental mechanisms.

Specifically, the formation of social groups was—and still is—necessary for survival. Accordingly, there is a fundamental tendency to identify with ingroups, those social groupings of which one is a member by birth or community, and to distinguish fellow ingroup members from those in outgroups, those foreign social groupings, tribes, or communities posing a threat to survival, particularly when resources are scarce. The deeply rooted nature of ingroup identification is revealed by so-called minimal group research, which reveals that even the color of clothing or the flip of a coin can invoke strong tendencies to align with like members and castigate those in the outgroup (Brewer, 1979; Tajfel, 1982).

When an outgroup member poses actual or symbolic threat to the ingroup perceiver, the likelihood of prejudice and stigmatization is increased considerably (Stangor & Crandall, 2000). In the case of serious, psychotic-proportion mental illness, the threat value of out-of-control, irrational symptoms may be palpable, even at the level of physical harm. In the case of other forms of mental disorder, however, which are not as overtly threatening, the very term mental illness conveys connotations of loss of reason, despair, weakness, and dependency, indicating symbolic threat. In fascinating research, Solomon, Greenberg, and

Pyszczynski (1991) showed that harsh judgments against outgroup members are strongly intensified when thoughts of death or mortality are primed in perceivers. This tendency may be particularly strong when the outgroup suffers from physical deformities or extremes of behavior, which may remind perceivers directly of the fragile and transitory nature of health and of life. This provocative idea incorporates existential, meaning-based perspectives on the types of situations and interpersonal interactions that are likely to elicit harsh, brittle reactions against marked individuals.

Dimensions of Stigmatization

Several features of castigated traits and conditions have major implications for their propensity to be stigmatized (see the seminal exposition by Jones et al., 1984). As noted earlier, the *concealability* of a stigmatized attribute raises anxiety regarding decision making with respect to openness versus disclosure (Goffman, 1963). Furthermore, the *threat* or *peril* induced by the mark has strong implications for stigmatization. Indeed, when pervasive cultural stereotypes emphasize the dangerousness and potential for violence of persons with mental disorders (see section on cultural indicators of stigma), the perception of threat, and of the potential for *disruptiveness* in social interchange, is magnified. Another core dimension is *aesthetics*; conditions that lead to bodily disfigurements have often received great stigmatization (see subsequent section on evolutionary psychological perspectives).

The final two dimensions from the taxonomy of Jones et al. (1984) are of particular relevance for mental disorder. First, the *course*, or longitudinal stability, of the mark in question is typically related to the propensity for stigmatization, in that conditions viewed as long-lasting or chronic are far more likely to be castigated than transitory states. In the case of mental disorder, the predominant view in the field—and in the minds of the general public—is that most variants of mental illness are chronic, lifelong conditions, fueling high levels of stigmatization. The actual evidence, however, is complex. For example, whereas mood disorders are highly likely to be recurrent, great numbers of individuals with such conditions have protracted periods that are relatively symptom-free (Goodwin & Jamison, in press). And Schizophrenia, long held to be a persistent condition marked by progressive, inevitable deterioration (see Neale & Oltmanns, 1980, for historical perspective), is now known to yield at least partial resolution in a significant proportion of individuals (Davison, Neale, & Kring, 2004). As for disorders of childhood onset, Attention-Deficit/Hy-

peractivity Disorder (ADHD) usually persists into adolescence, but adult outcomes are hugely varied (Mannuzza & Klein, 1999). Conduct disturbances are chronic in a small subset of youth who tend to have multiple, interacting risk factors spanning biological, psychological, and environmental domains, but most youth with aggression and conduct problems show a course that is largely limited to adolescence (Moffitt, 1993). Autistic Disorder, on the other hand, has a more uniformly negative prognosis, although early intervention may make a real difference in some cases (Klinger, Dawson, & Renner, 2003). In short, the view that all types of mental illness yield inevitable, chronic maladaptation is a distortion; promotion of the malleability and treatability of mental disorders is an important goal.

Second, a particularly crucial dimension is related to the *origin* or cause of stigmatized conditions, as well as the closely linked feature of their perceived *controllability*. Attribution theory is clear in this regard: Negative behavioral traits or features that are believed to arise for reasons outside the individual's personal control should elicit sympathy and concern, whereas those that are directly controllable will engender resentment and castigation. Weiner, Perry, and Magnusson (1988) present clear experimental evidence in this regard: Disabling conditions viewed as out of the individual's control (i.e., physical deformities) are likely to be met with compassion, whereas those linked to personal blame (i.e., behavioral or mental problems) generate rejection and hostility (see Corrigan et al., 2000, for further extrapolation to mental disorder).

Along with the considerable advances in neuroscience and genetics, this attributional perspective is clearly a reason for the promotion of efforts, in recent decades, to portray mental illness in medical model terms, as set of conditions analogous to physical illnesses or as "brain diseases" (Johnson, 1989). Indeed, such views are strongly supported by advocacy groups. I hasten to point out, however, that an unthinking rush to recast all mental disorder in reductionistic, biogenetic terms is no panacea for reducing stigma. For one thing, certain traits—most saliently, racial characteristics—that are clearly outside personal control have been among the most castigated and disparaged conditions in the history of our species. For another, it may be an uphill battle to convince the general public that constellations of behavior and affect are actually the products of genes and temperament, given the predominant cultural view that personal effort and volition are the sources of most behavioral displays. And even if a large segment of the populace is convinced that strongly heritable, biologically

based proclivities underlie much of mental disturbance, there is no guarantee that benign attitudes will follow.

First, at its extremes, such a causal model is reductionistic, failing to account for the transactional nature of the development of nearly all forms of psychopathology (Cicchetti & Cohen, this *Handbook*, Volume 1). Second, for reasons that should become clearer upon reading the forthcoming section on evolutionary perspectives on stigma, ascriptions to genetic etiologies and exclusively neural loci for mental illness may actually fuel a backlash, such that interpersonal responses will be harshly punitive (e.g., Mehta & Farina, 1997). The headline version of the reasoning behind this seemingly paradoxical state of affairs is that an exclusively biological perspective appears to promote the views that mental disorder is chronic, unrelenting, and hopeless (Phelan, Cruz-Rojas, & Reiff, 2002) and that mental illnesses are linked with genetic flaws, rendering the individual somehow less than fully human. Thus, although it would appear to be preferable to ascribe the causal locus of mental illness to biological proclivities rather than personal weakness, that is, to uncontrollable rather than controllable factors (Weiner et al., 1988), an exclusive attribution to deviant genetic makeup may be far from a panacea. Much more research needs to be done on the complex nature of control attributions and stigma related to mental illness.

Key Aspects of Stigma

Abridged from the discussion in Hinshaw (2006), I present information on several additional mechanisms and processes related to stigmatization, particularly as related to mental illness.

Pervasiveness and Implicit Stigma. The most marked and castigated conditions in a given society are likely to yield to widespread agreement from members of the culture as to their devalued status (Crocker et al., 1998). In other words, stereotypes about devalued groups are extremely *pervasive*. Especially given the access to print and visual media in modern societies, but also through storytelling, literature, and folklore in less Westernized cultures, there is typically widespread consensus on the racial, religious, and behavioral subtypes that are devalued and shunned. As a result, nearly all members of a society are confronted with images of the stereotyped group, children learn of these images at young ages, and the views of such negative characteristics become overlearned.

An upshot of this pervasiveness is that stereotypes and negative attitudes come to be automatically induced when

an outgroup member is identified or recognized (Crocker et al., 1998). Such automatic induction is likely to yield strongly conditioned emotional and behavioral responses, experienced unconsciously (Fiske, 1998). Furthermore, conscious efforts to suppress the automatic stereotypes in question may backfire when the perceiver has limited or overtaxed cognitive resources, fueling a paradoxical over-accessibility of the negative stereotype (see Wegner, 1997). Indeed, what are now termed *implicit* stereotypes and prejudices are those that are unconscious and overlearned as opposed to consciously and overtly expressed (Greenwald & Banaji, 1995). A wealth of current research in social psychology relates to implicit stereotyping and prejudice, particularly with respect to racial/ethnic perceptions. Measures of implicit attitudes comprise reaction-time tests that capture associations made without conscious introspection (e.g., Dasgupta & Greenwald, 2001; Greenwald, McGhee, & Schwartz, 1998; Greenwald, Nosek, & Banaji, 2003). Understudied, however, are the presence and pervasiveness of implicit attitudes toward individuals with mental disorder.

Ambivalence. A second key feature of stigmatizing reactions is the *ambivalence* inherent in their display (Hebl, Tickle, & Heatherton, 2000; Katz, 1981). The argument is as follows: Social valuations of outgroups are inherently complex, balancing compassion on the one hand and harsh judgment on the other. Many, if not most, members of modern society hold two often conflicting values: (1) egalitarianism, the belief in the equal worth of all humans and the equal opportunities that should be available to all members of society, versus (2) individualism, the belief that individual efforts are essential to personal advancement and are rewarded by monetary and social gains. Egalitarian views should yield sympathy, identification with victims, and efforts to correct social injustices that led to discrimination, whereas individualistic views will turn this perception on its head, such that members of stigmatized groups will receive blame for insufficient efforts on their own behalf.

Thus, confrontation with a member of a stigmatized group will tend to elicit ambivalence: the co-occurring display of sympathy and castigation. Reactions to stigmatized persons will be unstable (shifting between empathy and revulsion), extreme, and variable across time. It may take only a small stimulus (e.g., witnessing one additional member of a stigmatized group) to shift an initially positive response to a castigating one, or vice versa. Through a series of experimental manipulations, investigators have shown that responses to stigmatized persons are fluctuating and volatile, reflecting an underlying ambivalence toward the

castigated individual (Katz, 1981). This complexity makes for clear difficulties in investigating, much less reducing, stigma. Yet the presence of at least some initial compassion for stigmatized individuals gives hope, as it provides a starting place for intervention efforts.

With respect to racial and ethnic bias as well as discrimination against women, social changes in recent years have fostered a different set of social standards for what is acceptable in terms of publicly displayed attitudes. Thus, expressed racism or sexism may be far more masked than the overt, bigoted expressions that were formerly commonplace. Proponents of the concept of “modern” or “symbolic” prejudice or racism hold that such attitudes are expressed via conservative political views emphasizing individual responsibility or meritocratic beliefs rather than direct sentiments of antipathy toward the ethnic outgroup. Gaertner and Dovidio (2000) describe an important variant termed “aversive” prejudice or racism, in which an individual consciously committed to nonstigmatizing views still holds overlearned, unconscious, negative attitudes that emanate from cultural exposure to negative stereotypes, which may “leak” when there is no clear set of cues to show egalitarian expression. Such expressions reflect the deep, even unconscious ambivalence in members of modern society regarding prejudicial attitudes and emotions. Although it is still largely permissible to stereotype and castigate persons with aberrant behavior patterns or mental disorders, implicit attitudes may become the predominant means of castigating such individuals as social mores change in the future, as such attitudes may predict discrimination more than does their overt expression, which tends to be colored by social desirability and secular trends. Thus as noted, implicit as well as explicit attitudes and biases need to be emphasized in the next generation of research investigations.

Motivations for Stigma: Cognitive Schema, Self-Esteem Enhancement, and Institutional Supports. Why do members of ingroups castigate and stigmatize those in outgroups? As postulated by Allport (1954), ingroup identification does not require outgroup derogation. Yet several psychological and social proclivities often dictate that the two processes become intertwined:

1. *Social cognitions:* There is an overwhelming amount of social information in our everyday social worlds, and humans have highly developed cognitive structures and processes for dealing with the barrage of social information surrounding them (see Myers, 1998). These include strong tendencies to categorize the world through tem-

plates, which are termed, in relation to fellow humans, social *schemas*. People therefore make quick judgments about individuals from different towns, those with different hair color, or those who are of higher or lower social status on the basis of the schemas formed about such groups.

Such ways of perceiving the world, which can quickly become stereotypes, preserve cognitive resources when perceivers are tired, pressed for time, or cognitively or emotionally engaged with other stimuli or decisions. This kind of categorizing leads people to see those from foreign social groups as “all the same,” exemplifying the *out-group homogeneity* effect, whereas ingroup members are perceived as distinct and individualized (Ryan, Park, & Judd, 1996). Another cognitive tendency is to make linkages between rare, negative events (e.g., violence, aggression) and other infrequent categories (e.g., minority groups, perhaps including those with mental disorder), because of the distinctiveness of both (Haghighat, 2001; Stoessner & Mackie, 1993). Such processes are activated quickly and unconsciously; the resultant cognitive processing, which is schema-driven and automatic, serves to preserve cognitive resources.

In short, some roots of prejudice and stigma do not require grossly unequal social conditions or discriminatory practices but stem from normal patterns of social cognition, particularly those linked to schema-driven processing. Note, however, that the presence of these tendencies does not mean that resultant stigmatization is inevitable or unchangeable. Indeed, people can and do invest the cognitive and emotional energy necessary for effortful social processing, whereby complex information about individuals is integrated into balanced, thoughtful judgments rather than quick stereotypes (Devine, 1989).

2. Self-esteem enhancement: Evidence exists that derogation of outgroup members serves to bolster not only social identity with the ingroup but also one's self-esteem. In an intriguing series of studies, Fein and Spencer (1997) showed that individuals who had received information damaging to their own self-esteem made disparaging characterizations of members of stereotyped outgroups, and such negative evaluations served, reciprocally, to bolster and restore their own self-image. Thus, stereotypes may provide a viable tool through which self-esteem maintenance and enhancement can occur when a person has suffered a blow to his or her own self-worth. Furthermore, this tool does not engender much remorse, because the stereotype is accepted and reinforced throughout the culture. Interestingly, this phenomenon may be most prominent for those whose self-esteem is initially high rather than low (Baumeister, Smart, & Boden, 1996).

Note, however, that self-esteem enhancement is not a sufficient criterion on which to base a model of the functions of stigma and stigmatization. For instance, it does not explain the strong consensus that tends to develop in most cultures about the recipients of denigration and stigmatization; other social processes must be at work to shape the consistency of targets of stigma. Also, it does not deal well with the tendencies for outgroup members to believe the stereotypes foisted on them and, at times, to display lowered self-worth in terms of the denigration they experience. In short, enhancement of self-esteem may well be a motivator for at least some ingroup members to participate in derogation and denigration of the outgroup, but research on the applicability of this phenomenon to mental disorder is sparse.

3. Institutional supports: I noted earlier that prejudice and stigmatization may follow from structural inequities in society, serving as system-justification mechanisms. In addition, cultures typically reveal institutional supports for discrimination. If segregation (or, indeed, slavery) is the law of the land, then castigating, system-justifying processes related to derogation of the disenfranchised group in question are likely, in order to rationalize the legally mandated unequal treatment. Consider other kinds of supports that are simply part of cultural life. For example, the crayons labeled flesh-colored in young children's coloring supplies are light tan/pink in hue, consistent with the coloring of European Americans but not other ethnic groups. Dolls have also typically been “White” in color. During the middle of the twentieth century, African American children were noted to select skin colors for drawings that were closer to the White norm than their own skin color (Clark & Clark, 1950). Media portrayals provide another source of cultural modeling and strong institutional support for pervasive stereotypes. In this regard, the overwhelming portrayal of persons with mental disorders in the print and visual media is one of violence, unpredictability, dangerousness, and irrationality (Wahl, 1995). Clearly, societal and institutional factors motivate stigma.

Another macro variable pertains to *economics*. In brief, it is likely that there are harsher reactions to deviance during periods of difficult economic circumstances than during affluent times (see Jones et al., 1984). In what is termed “realistic group conflict theory,” competition for scarce resources motivates high levels of outgroup derogation (Sherif & Sherif, 1953; Stangor & Crandall, 2000). In fact, Hovland and Sears (1940) found evidence for a statistical association between economic indicators such as the price of cotton in the southern United States

and the number of lynchings of African Americans during corresponding periods, whereby lower prices were associated with a rise in such murders. Subsequently, Hepworth and West (1988) reanalyzed the same data with more sophisticated statistical techniques, concluding that although the original findings may have exaggerated the magnitude of the associations, the core conclusions withstood stringent statistical controls. With respect to mental disorder, society provides sizable amounts of money and resources for individuals with serious mental illness as well as mental retardation, although not to the extent of parallel expenditures regarding physical illness. During times of economic hardship, the willingness to provide such support may well wane. This is clearly an empirically testable question.

Evolutionary Psychology and Stigma

Is there a deeper, more fundamental way in which humans are predisposed or programmed to detect, identify, and shun fellow humans with deviant behavior patterns? In recent years, interest has surged in accounts of human behavior that emphasize its naturally selected roots (see deWaal, 2002, for promises and cautions regarding this perspective). Indeed, evolutionary psychology has entered the debate about stigma (Fishbein, 2002; Kurzban & Leary, 2001; Neuberg, Smith, & Asher, 2000), and the implications are provocative. The near universality of the stigmatization of mental illness provides clear impetus to consider evolutionary processes as roots for such social exclusion.

From an evolutionary point of view, humans have been selected over their history not only for prosocial tendencies but also for certain limitations on social interchange, as indiscriminate affiliations may pose a survival threat. That is, members of our species have always needed others for procreation, investment in parenting, and cooperation to achieve mutual goals, but there are real costs to some social interactions, including (1) competition over shelter, economic resources, and mating partners; (2) the potential for aggression and violence; and (3) the contraction of parasites or contagious diseases. According to Kurzban and Leary (2001, p. 188):

There exists a collection of discrete, domain-specific psychological mechanisms that have evolved to solve adaptive problems associated with sociality. . . . Together, the behavioral manifestations of these exclusionary mechanisms generate the phenomena that have fallen under the rubric of stigmatization. . . . Furthermore, because humans everywhere are endowed with the same psychological systems, we should expect

cross-cultural similarities in behavior driven by the similarities in underlying psychological architecture.

Underlying this perspective are two core premises: Humans require brakes on unbridled sociality, as indiscriminate social contacts may compromise survival, and many other animal species have been observed to display exclusionary strategies against conspecifics displaying certain forms of deviant behavioral patterns (Neuberg et al., 2000).

The attributes most likely to engender naturally selected exclusionary mechanisms are those that presumably posed clear threats to early human societies: (1) fellow humans who foster parasitic infestation (revealing themselves through unsightly appearance or display of atypical behaviors), (2) those who provide low social capital or direct exploitation of social partners, and (3) members of rival nationalities or cultures. Intriguingly, these three hypothesized types of social exclusion modules are nearly identical to the three kinds of stigmatized attributes posited by Goffman (1963): abominations of the body, character flaws, and "tribal" characteristics related to differences in skin color or place of origin. Thus, whereas social psychological accounts of stigma have largely ignored the typology of Goffman, the evolutionary model has resurrected them.

Kurzban and Leary (2001) postulate that the characteristics of mental disorder foster the first two types of exclusion tendencies. Specifically, behavioral and physical dishevelment, or even overly compulsive behavioral patterns, associated with serious mental disorders may trigger primitive fears of infestation or contagion (indeed, birds and primates signal parasites by excessive grooming). Furthermore, behavioral excesses, erratic and unpredictable behavior, and poor inhibition—all linked with some forms of mental illness—suggest both low social status and the potential for exploitation of others, putatively spawning the fear of being cheated. On the other hand, the kinds of features related to tribal or nationalistic differences are not, on the face of it, related to mental illness exclusion modules.

The specificity of predictions from evolutionary models is compelling. First, *emotional responses* are postulated to differ across the three detection mechanisms. Those suspected of spreading parasites or disease will elicit disgust, violators of dyadic exchange (i.e., cheaters) are predicted to evoke anger (related to the violation of the implicit or explicit social contract), and members of tribal outgroups will tend to elicit fear and hatred as a function of their threat to the home group or nation. Second, with respect to *behavioral responses*, the clear expectation is that those be-

lieved to be contagious will be avoided or shunned, those with character flaws will be punished for their social violations, and those in outgroup tribes will be retaliated against and exploited (Kurzban & Leary, 2001). In terms of mental disorder, which is linked to both social contract violations and some types of parasitic infection avoidance—but not, by and large, to national or tribal status—the expected social responses would range from avoidance to punishment but would not entail the types of exploitation reserved for national or ethnic groups who are in conflict with the in-group or home tribe.

Consider, however, the scenario in which mental illness is attributed to reductionistic, biogenetic medical models, that is, when it is viewed as the product of flawed genes or biochemistry. Some evidence exists from attitude surveys that those individuals who ascribe mental afflictions to biological/genetic causal factors are less likely to blame or desire social distance from individuals with mental illness, as might be expected from attribution theory (see Martin, Pescosolido, & Tuch, 2000). On the other hand, if such biogenetic attributions are made in extreme, reductionistic fashion, afflicted individuals may come to be viewed not only as chronically diseased and therefore beyond intervention but also as a separate, inferior, and even subhuman group. Thus, despite the supposed attributional advantages of making medical model ascriptions for deviant behavior, it may be the case that overzealous ascriptions to medical/genetic causes fuel a harsh and exploitive set of behavioral responses, at the level of tribal stigmas. Recent empirical investigations show that exclusively genetic/biomedical attributions for mental disorder fuel social distance and extremely punitive responses (Dietrich et al., 2004; Mehta & Farina, 1997; Read & Harre, 2001; see also Phelan et al., 2002). Furthermore, the harshly punitive and even genocidal tendencies of the eugenics movement in the early decades of the twentieth century, which originated in Britain (spreading quickly to the United States) and which then expanded horribly in Germany, stemmed directly from views of mental illness that emphasized their hereditary, immutable origins (Black, 2003; Kevles, 1985).

Overall, the evolutionary perspective is a bold attempt to account for the universality of many forms of stigmatization, particularly those related to mental illness. As currently proposed, it is not particularly developmental; understanding how children and adolescents come to perceive attributes that may be stigmatizing in terms of behavioral deviance is an important research topic. Although this viewpoint is pessimistic to the extent that it posits inherent human tendencies to exclude, shun, and even punish other

persons with certain forms of behavioral deviance, even advocates of evolutionary models agree that such proclivities do not inevitably portend that humans will act on these exclusionary modules. Indeed, as discussed by Neuberg et al. (2000), stigmatization modules that may have been adaptive in the environment of evolutionary adaptation are often extremely maladaptive in the present era. Their presence does not imply that they are correct or right in current times. Humans need to learn how to overcome such ingrained proclivities if stigmatization is to be reduced.

Summary

Stigma is multifaceted, complex, and overdetermined. Major theoretical advances in social psychology have propelled the understanding of stigma processes, which have roots in social cognition, intergroup processes, and social hierarchies. In addition, natural selection may have shaped fundamental exclusion tendencies in humans, some of which appear directly related to the propensity for stigmatization of mental illness. Whereas the roots of stigma appear to lie deep within (1) typical modes of social cognitive processing, (2) rules of social interchange between in-groups and outgroups, and (3) the social and political structures that have been created in all human cultures, the degrading, humiliating, and terrorizing aspects of prejudice and stigma are not predestined. Because stigma typically involves deep ambivalence, involving a mixture of empathy and concern with fear and hostility, promoting identification and sympathy is a key goal.

HISTORICAL PERSPECTIVES ON STIGMA

Too often, historical accounts portray the past in sweeping terms. For instance, the naturalistic, medical models of ancient Greece and Rome are juxtaposed with the chaos and ignorance of the Dark Ages; moralistic crusades against deviance in the middle of the previous millennium (including witch hunting) are contrasted with the humane treatment of the late Enlightenment or the current era. In fact, such global trends contain many distortions, as does the perspective that history moves inexorably toward progress and rationality. Cycles of reform and retrenchment lie closer to the truth, in which themes of biological versus environmental causation, personal control versus lack of control, and punitive treatment versus humane care wax and wane over time (Allderidge, 1979; Hinshaw, 2006).

One of the challenges of the present is to plan for realistic reform that can yield lasting change rather than counterreactions, retrenchment, and despair.

Despite the clear presence of cycles of human response to mental illness, the predominant theme across recorded history regarding the treatment of persons with mental disorder includes a depressing tendency toward exclusion and punishment, as would be suggested strongly by evolutionary psychological accounts. Indeed, once people began to write down narratives of their cultural practices, descriptions of individuals with atypical behavior patterns soon followed. Ancient texts, such as the Bible, provide richly detailed accounts of mentally disordered behavior, which portend modern classification systems with great accuracy.

It may be the case that a good deal of unofficial history has been marked by attempts at custodial care of persons with mental illness at home, but official accounts are filled with cruelty and banishment as primary modes of response (Zilboorg, 1941). I can present only a brief summation of key historical trends to illuminate both the core tendencies toward maltreatment and the reforms that have emerged from time to time. One of the core themes from a careful reading of history is that views of and treatments for mental illness have lagged considerably behind mainstream scientific and humanistic advances throughout history; the stigma surrounding the entire topic has greatly limited the spread of human knowledge to this subject matter (Hinshaw, 2006). During the Renaissance, for instance, the explosion of scientific and artistic advances was not matched by parallel improvements in the understanding or care of those with mental illness, who continued to be viewed with a blend of moralistic, superstitious, and primitive biological perspectives (Zilboorg, 1941). I also emphasize the important point that children and adolescents with behavioral aberrations have been at risk for a double stigma, in that fear and castigation of mental illness have been compounded by the generally low status of children throughout history.

Adults with Mental Disorder

Across nearly all historical periods, a core perspective on disturbed behavior has been that it emanates from possession by evil spirits or the devil. Given their moralistic framework, such demonologic views have been associated with harshly punitive social responses. Yet, in some instances, religious and moral perspectives have been linked to hopeful, humane care. For example, monasteries were sometimes refuges during the Middle Ages, and the theory

and practice of “moral treatment” in the early nineteenth century had both humanitarian and religious overtones (Grob, 1994).

In terms of biological perspectives, one of the first recorded naturalistic views of mental disorder occurred in classical Athens, when Hippocrates posited that mental illnesses originated from imbalances in one or more of the four major bodily humors. This theory was accompanied by the view that afflicted persons required careful diagnosis, compassion, and humane care emphasizing restoration of bodily balances. On the other hand, the lack of sophistication of biological theorizing meant that such practices as bloodletting and purging (through emetics) were primary treatments for the next 2,000 years. In addition, exclusively biological views have also been associated with the perspective that mental illness is hopeless and chronic, fostering the belief that isolated custodial care in institutions is the primary treatment option.

Thus, there is no simple, one-to-one association between etiologic views of mental illness and humane versus cruel social responses. What appears necessary in the future is the promotion of multifaceted views of mental disorder that emphasize biological vulnerabilities as causal factors, plus environmental risks as precipitants and personal and family responsibility necessary for ultimate outcome (Hinshaw, 2006).

History is replete with instances of cruelty and maltreatment toward persons with mental disorder. One of the predominant views of so-called insanity and lunacy in Western cultures has been that the afflicted individual had lost his or her fundamental abilities to reason, thereby spurring the belief that he or she was less than fully human. Hence, many treatments involved terror and fright to spur the individual back to full mental faculties. At the level of physical sensation and pain, it was believed that beatings or subjugation to extremes of cold in unprotected winter quarters did not affect the mentally disordered in the same ways as they would affect normal individuals (Zilboorg, 1941).

Institutional care, first in special wards of general hospitals and then in asylums created for the insane, spurred excursions by citizens of the nearby cities to observe, for an admission fee, the raving, psychotic, and “amusing” behavior of the inmates. Given the clear parallels with tours of zoos, the underlying belief was that the persons in the institutions were less than human. Even some of the great liberators of the mentally ill—Pinel in France, Tuke in England, Rush in the New World—held harshly authoritarian views of the childlike nature of persons with mental illness (Hinshaw, 2006). It is important to note that more

progressive and humane perspectives on the care of mental illness often emerged from non-Western cultures, particularly Middle Eastern nations.

A strong custom in many cultures was to force persons with mental illness outside of cities, towns, and villages to wander the countryside, begging for subsistence. Hence, shunning and exclusion were strong undercurrents of response to mental disorder (Zilboorg, 1941). As with institutional care in distant asylums, such banishment served to place the issue of mental disorder outside of the everyday awareness of most citizens, constituting another legacy of stigmatization.

The twentieth century was marked by the rise of increasingly secular, and increasingly scientific, views of mental illness, as evidenced by the expansive growth of the fields of psychology and psychiatry. One core trend was the eugenics movement, which originated in the United Kingdom but which quickly spread to the United States (Black, 2003). The underlying belief in the genetic locus of mental retardation and mental illness led to the passage of mandatory sterilization laws in a majority of states and set the stage for even more stringent measures in Nazi Germany, where hundreds of thousands of persons with mental illnesses were not only sterilized but annihilated (Kevles, 1985). Once again, reductionistic perspectives on biological loci of mental disorder have been associated with extremes of cruelty.

At the same time, psychological perspectives were emerging, most notably the psychoanalytic views of Freud and his followers. Although these perspectives, like the biological perspectives just discussed, tended to rid mental illness of demonologic overtones, for much of the century they directly implicated poor parenting as responsible for most forms of mental disturbance. In fact, conditions such as Autism and Schizophrenia were held to result directly from faulty, cold, and unresponsive parenting, fueling decades of direct parental stigmatization regarding the mental disorders of their offspring (e.g., Bettelheim, 1967). Other theoretical models, such as behaviorism, were also extreme in their positing of environmental determinants of mental illness. Note too that the very term “mental illness,” including its dualistic separation from physical conditions, often implies that the underlying conditions are “in the mind” and not real illnesses.

By the later decades of the twentieth century, biomedical/genetic frameworks regained ascendancy, fostered by major advances in neuroscience, neuroimaging, biological psychiatry, and molecular genetics. Such views have prompted the perspective that mental illnesses are “diseases like any other,” beyond volitional control, with the hope of a

resultant reduction in personal and family blame (see Johnson, 1989, for promotion of the view of mental disorders as brain diseases). As highlighted earlier, however, unidimensional, reductionistic biomedical views are often paradoxically associated with extremely punitive responses, probably because they cast persons with mental illnesses as chronically flawed, deviant, and even subhuman and invoke the kinds of tribal stigmas usually reserved for racial and ethnic minorities. As noted later in the chapter, developmental models of mental illness have the potential to promote more accurate perspectives.

Finally, I note the deinstitutionalization movement of the past 40 years. The advent of psychotropic medications, plus the emergence of a community mental health model, led to the curtailing or closing of public hospital settings for children and adults with mental disorder from the 1960s through the present day (Grob, 1994). Whereas few would argue against the core tenets of this movement, including its goal of ending the dehumanizing, isolating conditions of mass institutionalization, the reality is that governments have often viewed deinstitutionalization as a primary means of cost saving (e.g., Appelbaum, 2002). The resultant absence of needed community-based services has allowed severely mentally ill adults, adolescents, and children to exist in the kinds of underfunded community residences—or even on the streets—that are the legacy of cost-cutting measures. Thus, the great hopes for the deinstitutionalization movement of the second half of the twentieth century have too often been met with retrenchment and despair. Note a parallel with the extreme promise of the campaign of Dorothea Dix in the 1800s to replace almshouses and prisons with specially designed mental hospitals: The very institutions she initiated came to be distant, fortress-like, total institutions that often promoted cruel treatment and hopelessness. Stigma has doubtless been increased by community care models that emphasize cost savings over integrated, well-funded programs and that have allowed countless persons with severe mental illnesses to be left to city streets or suboptimal and even subhuman community residential care.

Children with Mental Illness

What has been the plight of children—and, in particular, children with mental disturbances—across history? One sobering perspective is that relatively few children have survived childbirth, infancy, and childhood across most cultures and historical periods, limiting parental attachment to and investment in young children. Even as late as seventeenth- and eighteenth-century America and Europe,

the clear majority of children did not survive until age 4 or 5 years (Donohue, Hersen, & Ammerman, 1995). Children have also been viewed as miniature adults in many cultures, with childhood viewed as a brief period of time before youngsters were, of necessity, brought into the labor force (Aries, 1962). As a result, children's rights have been virtually nonexistent, with extremely high rates of harsh treatment, including exploitation, neglect, abandonment, and abuse (Phares, 2003). Indeed, a common practice throughout multiple cultures has been the practice of infanticide, the intentional killing of babies and young children, when family size became too large and when providing for yet another mouth to feed was not possible. This practice was much more likely to occur when the child possessed physical or behavioral deviance. Short of the killing of deviant or disabled children, evidence is strong that such youth were treated with scorn and derision (Donohue et al., 1995).

Only in the past several hundred years has childhood been viewed as a distinct developmental phase, and only in the past century and a half have movements to curtail child labor and mandate education been in place. Indeed, no recordings of children's games or children's literature are evident from the Dark and Middle Ages, suggesting strongly that children were viewed primarily as adults of small stature, with no special accommodations made to their developmental status and with a high premium placed on their ability to provide labor as soon as possible. Youth were commonly put to full-time work by the age of 6 years, and marriages were arranged before adolescence to assure economic well-being for families. Children were often sold into slavery, and beatings were routinely accepted as discipline. In agrarian societies, as soon as children could provide labor, they typically did (Donohue et al., 1995). With the advent of industry in the past several hundred years, children provided a cheap source of labor until restrictions on such practices were recently instituted.

Furthermore, until only the past few decades, parents have had the right to physically and emotionally devastate children, largely because of the view that disciplinary matters within a family are inherently private (see Helfer & Kempe, 1968). The brutalization of children has been such a part of many cultures that intergenerational patterns of maltreatment of children have been nearly endemic (Rhodes, 1999). Note that, in the late nineteenth century, the Society for Prevention of Cruelty to Children was founded *after* the establishment of the Society for Prevention of Cruelty to Animals, demonstrating again the strongly held notion that family business was subject to privacy and that the rights of parents to perform nearly any

act of cruelty on children was unchallenged. Indeed, it has only been in the past 125 years that social institutions have been created to deal with the emotional and behavioral problems of children (Levine & Levine, 1992). Many special protections for children that are taken for granted today have been put in place only during the past century, including child labor laws, universal compulsory education, and child guidance centers and specialized facilities for dealing with child mental health.

In fact, throughout history, when children, typically lacking any protected status, have displayed mental illness, the combination has led to extremes of castigation and cruelty. Even during the modern era, as noted earlier, the growth of child psychology and child psychiatry served to harshly stigmatize parents for causing the mental disturbances of children. Revealing the dual stigmatization of both children and mental illness, basic and applied research on children's mental disorders has lagged well behind parallel efforts for adults.

In recent years, the biological *Zeitgeist* has replaced environmental views of etiology, tempering a great deal of family and parental blame for mental disorders of youth. Yet, the stigma and shame encountered by far too many families coping with a child suffering from mental disturbance have not abated (Lefley, 1992), and service utilization rates have been extremely low for children and families (New Freedom Commission on Mental Health, 2003). Thus, the legacy of the joint stigmatization of children and mental illness continues. In short, whereas mental disorder has incurred banishment and harsh treatment throughout history, the plight of children and adolescents has been even worse, given the low status and utter lack of power afforded to youth. Stigma of child and adolescent mental disorders must contend with a compound struggle: the general effort for children's rights and the specific attempt to guarantee rights to persons with mental illness.

EMPIRICAL AND CULTURAL EVIDENCE FOR STIGMA

With this historical information in mind, what do empirical research investigations reveal regarding the actual presence of stigma during our current, modern era? And what does a broader examination of cultural, linguistic, and institutional practices uncover? I begin with attitudes of the general public, then highlight families and mental health professionals, and conclude with examination of less empirically based but nonetheless essential evidence that stems from general practices in the culture.

Empirical Research

Empirical investigations have focused on the responses of several groups: the general public, individuals experiencing mental illness, family members, and mental health professionals.

General Public

A long tradition of research on stigma began to emerge in the 1940s and 1950s. Early investigators often utilized the methodology of presenting written case history vignettes to probe respondents' abilities to identify whether mental illness was present as well as their attitudes toward mental disorder. Outcome measures typically included (1) social distance scales, whereby respondents appraised the degree of desired contact with or distance from an individual so depicted; (2) informational and attitudinal measures; and (3) semantic differentials, for which respondents would choose between opposite pairs of adjectives, such as "dirty" versus "clean," to describe the vignette (see, e.g., Nunnally, 1961). The overarching conclusion from the early era of research on public attitudes was the devastating nature of the stigmatization experienced by individuals with mental illness. That is, once members of the public could identify a certain pattern of behavior as representing mental disorder, negative and rejecting responses were highly likely. The clearest explanations for such stigmatizing attitudes were the unpredictability and threat value of the behavior patterns in question (Rabkin, 1972, 1974). Ignorance and intolerance of mental illness were found to be associated with lower levels of respondent education, although negative attitudes were certainly not restricted to those members of society with poor educational backgrounds. Furthermore, empirical studies revealed the presence of stigmatization even in mental health professionals and staff members, who had apparently internalized the general cultural messages of fear, distancing, and prejudice (see subsequent section). As stated by Rabkin (1972, p. 154), "In a very real sense, mental patients have taken the place of lepers as targets of public disgust, dislike, and rejection."

By the 1960s and 1970s, however, some investigators were finding that public attitudes, as revealed by questionnaire responses, were beginning to shift toward a more empathic and altruistic stance toward individuals with mental illness (see Crocetti, Spiro, & Siassi, 1971; Gove, 1982). Yet, a closer look at the empirical literature reveals that such conclusions were premature. First, research in which direct comparisons were made between persons with mental illness and other stigmatized groups (e.g., those with

physical diseases; ex-convicts) consistently showed that mental disorder was ranked at the bottom in terms of social acceptance (e.g., Albrecht, Walker, & Levy, 1982; Tringo, 1970). More recent studies reveal that only substance abuse and homelessness rival mental disorder in terms of stigmatization. Second, questionnaire responses may be greatly influenced by social desirability. Careful work by Link and colleagues (e.g., Link & Cullen, 1983; Link, Cullen, Frank, & Wozniak, 1987) revealed that the wording of typical questionnaires predisposes respondents to overrate their tolerance of mental illness. Furthermore, when participants hold the core belief that mental disorder is linked to violence, attitudes are highly denigrating. Thus, attitude scales may well underplay the actual extent of stigmatization. Third, and crucially, research on the behavioral (as opposed to attitudinal) responses of the public to mental illness has been strongly consistent in revealing tendencies toward shunning, devaluation, and discrimination. For example, the work of Farina and colleagues (Farina, Allen, & Saul, 1968; Farina, Gliha, Boudreau, Allen, & Sherman, 1971; Farina & Ring, 1965) revealed that even a participant's *belief* that interaction partners knew of his or her mental illness negatively influenced a subsequent encounter, exemplifying a self-fulfilling prophecy effect. A classic example of behavioral, as opposed to attitudinal, research is the experimental work of Page (1995), who, across 3 decades, found that landlords were far more likely to deny housing opportunities to potential renters who disclosed a history of mental hospitalization than to those who did not present such a history. In commenting on this work, Page decried the "naïve acceptance of interviews, surveys, or questionnaire-based data" (p. 67).

More recent research, both attitudinal and behavioral, has confirmed that although the general public appears to have gained basic knowledge about mental illness over the past decades, attitudes and behavioral responses are still highly prejudicial and stigmatizing (e.g., Crisp, Gelder, Rix, Meltzer, & Rowlands, 2000; Link, Phelan, Bresnahan, Stueve, & Pescosolido, 1999; A. H. Thompson et al., 2002; Wahl, 1999). Specifically, based on a large, representative sample of the U.S. population (sampled in the General Social Survey), the work of Link et al. (1999) reveals that depictions of substance abuse incur more social distance than do vignettes of Schizophrenia or depression—although all are associated with strong desire for social distance—and that stigma emanates from perceptions of violence linked with such conditions. Indeed, compared to the 1950s, the general populace of the United States is now more likely to link mental illness (particularly its most severe, psychotic

variants, such as Schizophrenia) with tendencies toward violence—and it is just such beliefs that fuel stigma and fear (Phelan, Link, & Pescosolido, 2000). This general pattern of stigmatization appears to be the case worldwide (e.g., Angermeyer & Matschinger, 1997; Guimon, Fischer, & Sartorius, 1999).

In terms of the basic question as to whether the behavioral display characteristic of mental illness or the label itself is more likely to be stigmatized, the answer is complex: When behaviors and the label are pitted against each other, the behaviors characterizing mental disorder receive more castigation and social distance. Yet, when the label occurs alone or in the presence of minimal behavioral disruption, stigmatization is strong, and, as just noted, the effects of the label are magnified greatly when respondents associate mental disorder with risk for dangerousness and violence (Link et al., 1987; Phelan et al., 2000).

With respect to children, the bulk of research on stigma has focused on the effects of diagnostic labels on the attitudes of social perceivers, both adults and youth. A number of investigations reveal negative effects of labeling on stigma-related processes. For example, Farrington (1977) showed that the label “delinquency” for youth displaying antisocial behavior had negative effects on eventual outcome (see Adams, Robertson, Gray-Ray, & Ray, 2003). Holguin and Hansen (2003) demonstrated the negative consequences of the label “sexual abuser” for individuals so termed. In fascinating experimental research, Harris, Milich, Corbitt, Hoover, and Brady (1992) had children in third through sixth grades interact dyadically with a peer. Experimentally manipulated were both the actual diagnostic status of the peer, who either did or did not have ADHD, and the child’s expectation for the peer interaction partner in the form of the label “behavior problem” or no label. Both factors (interacting with a peer with ADHD and holding the expectancy that the partner would have a behavior problem) negatively influenced the subsequent interaction, with the labeling effect indicative of stigmatization related to the expectancy of problem behavior. Thus, not only are children with behavioral and emotional disorders highly likely to receive peer rejection in response to the symptoms of their conditions (e.g., Erhardt & Hinshaw, 1994), but age-mates’ perceptions of labels related to mental illness fuel denigration and castigation (see also Milich, McAninch, & Harris, 1992).

Note that negative effects of labeling extend downward in age to infancy: Labeling videotaped infants as “cocaine exposed” yielded more negative adult ratings of the behaviors displayed than did no label (Woods, Eyler, Conlon, Behnke, & Webie, 1998). Similarly, labeling infants “de-

pressed” increased negative ratings, particularly if parents (fathers, in this case) showed symptoms of depression themselves (Hart, Field, Stern, & Jones, 1997).

Other investigations, however, suggest that labeling of child behavior problems is not always pejorative and may even have positive effects. MacDonald and MacIntyre (1999) showed that altering labels of mental disability and attention-disordered behavior did not influence participants’ evaluations of the behavior patterns that were depicted. In addition, Klasen (2000) found that for parents of children with ADHD, the diagnosis of the child was actually empowering, as it reduced parental blame and increased the likelihood of obtaining treatment. Indeed, appropriate diagnosis and responsive treatment can be liberating, particularly if they facilitate the opening of opportunities for future independence and life satisfaction (Hinshaw, 2002). Efforts to educate the populace about the realities of mental disorder and to promote egalitarian contact between persons with mental illness and the rest of society will be crucial for enhancing such receptivity, particularly for family members (see Hinshaw, 2006).

Developmentally, when do children recognize the concept of mental illness, and does their knowledge of or attitudes toward peers or adults with either behavioral deviance or the label of mental illness vary with age? Wahl (2002) has reviewed the rather sparse literature on this important topic. In brief, results are difficult to discern with precision because of varied instrumentation across investigations as well as a lack of reporting of psychometric properties of many of the attitudinal and social distance measures utilized. Generally speaking, young children do not have clear conceptions of the mental illness term, often confusing it with physical illnesses or mental retardation. Indeed, children in the early elementary grades often do not know the term mental illness at all, so that some investigators use the term “crazy person” (or variants thereof) as the independent variable. By the later elementary grades, more differentiated knowledge structures are beginning to emerge, such that mental disorders can be distinguished from other forms of deviance or illness. Yet stigmatizing attitudes and desire for social distance are clearly present from early ages. As stated by Wahl, “Even if young children do not know the precise definitions or characteristics of people with mental illnesses, they seem to know that they are undesirable and to be avoided” (p. 147). Intriguingly, some research indicates that the mental illness concept can be applied more readily by youth to adults than to children *per se*; it is therefore unclear how children attribute the deviant behaviors of peers with mental conditions. Overall, the pervasive influence

of public media on the early display of children's negative attitudes toward mental disorder is difficult to avoid as an explanatory factor (see Wahl, 2002; Wilson, Nairn, Coverdale, & Panapa, 2000).

Individuals with Mental illness

Distressingly, adults with mental illness are highly likely to have internalized many of the negative stereotypes and prejudicial attitudes related to mental disorder that are part of the general culture. They frequently report being the victims of overt or covert discrimination as well as harshly stigmatizing attitudes and general cultural practices related to prejudice (Read & Baker, 1996; Wahl, 1999). Furthermore, stigma and social rejection predict subsequent life adjustment problems for patients with mental illness, over and above initial symptom levels (e.g., Wright, Gronfein, & Owens, 2000). Of particular importance, the expectation of stigmatization predicts premature termination from therapy (Sirey et al., 2001). Secrecy about mental illness and withdrawal from social contact are two of the key coping mechanisms employed by persons with mental disorders in response to stigma; note that such reaction tendencies are likely to perpetuate, rather than overcome, stigmatization (Wahl, 1999). This kind of self-stigmatization may have far-reaching impact on the lives of persons with mental illness (Corrigan, 2004).

Largely unexplored are the various coping styles and strategies deployed by persons with mental illness in response to the stigmatization they receive (Corrigan & Watson, 2002; for a thorough review of identity threat theory in relation to other stigmatized conditions, see Major & O'Brien, 2005). Indeed, almost entirely unknown are the processes by which some persons internalize prejudice and stigma to a large degree, others apparently ignore such castigation, and still others view it as a call to social action. And, as noted by Wahl (2002), there is an utter dearth of research on the self-perceptions and coping strategies of children who have experienced mental disorder. Developmental factors are bound to be essential to such self-perceptions and coping strategies, constituting a major area for future research.

Families and Relatives

There is a growing database on family experiences of mental illness (e.g., Lefley, 1989, 1992; Tessler & Gamache, 2000; Wahl & Harman, 1989). Systematic research on this topic emerged in the 1950s (see Clausen & Yarrow, 1955). Stages of recognition of symptoms were noted, analogous to those in reaction to the development of physical illnesses, with initial anxiety and denial giving way to adoption of a

"sick" role and eventual rehabilitation. As reviewed by Kreisman and Joy (1974), the early years of work in the field focused on a variety of negative responses to relatives with mental disturbance, including fear and dislike, and a host of reactions in the relatives themselves, such as sensitivity to criticism by others, a perception of marginality (with few resources available to help their plight), and self-dislike. Concealment and secrecy were cited as extremely prevalent coping responses. In all, the ramifications of having a relative with mental illness were found to be considerable, encompassing Goffman's (1963) notion of "courtesy stigma," signifying the devaluation that attends to persons who are associated with a stigmatized group.

Investigators have distinguished two types of consequences to families of having a relative with mental illness: *objective burden*, comprising the financial costs, seeking of housing, and logistic negotiations needed to manage a relative with mental illness, and *subjective burden*, constituting the psychological pain, embarrassment, and mental anguish related to caring for the family member. Families report that subjective burden is the stronger of the two (Lefley, 1989; Tessler & Gamache, 2000; E. H. Thompson & Doll, 1982; for a cogent review of the impact of stigma on families, see Corrigan & Miller, 2004). This finding provides distressing evidence for the pervasive nature of stigmatization. Indeed, in the words of Lefley (1992, pp. 128–129):

In many cases mental illness in the family jeopardizes relationships with friends and neighbors; in extreme situations it may lead to an almost total social isolation of the family unit. . . . Emotional reactions to major mental illness in a family member frequently include bewilderment, fear, denial, self-blame, sorrow, grieving, and empathic suffering. . . . The added perception of stigma may elicit rage and resentment or intensify depression and social withdrawal. Normative ambivalence toward mentally ill loved ones—the typical swing between exasperation provoked by the patient's behavior, guilt at the reaction, and sorrow evoked by the patient's suffering—may be exacerbated by social stigmatization of families.

What is extent of family burden? In a telling comparison, Struening and colleagues (1995) documented that the subjective burden of those caring for seriously mentally disordered relatives was as strong as that related to a homeless relative and even more salient that associated with multiple sclerosis. Concealment is still a prevalent response among family members, with greater levels of stigmatization perceived by families with higher educational levels than those from lower socioeconomic strata (Phelan, Bromet, & Link, 1998), probably because of the

greater shame involved in having a relative with a low-status condition like mental illness in upper socioeconomic brackets. Siblings of adults who suffer from serious forms of mental disorder also carry a great deal of subjective burden, comparable to levels experienced by parents (Greenberg, Kim, & Greenley, 1997). Recent evidence indicates that courtesy stigma applies, at least to some extent, to parents of children with ADHD (Norvitis, Scime, & Lee, 2002). The overwhelming majority of caregivers believe that most members of society devalue persons with mental illness, with nearly half contending that society also devalues the family members of such individuals (Struening et al., 2001; Wahl & Harman, 1989).

Family burden and perceived stigma are not restricted to the United States. In Sweden, the majority of relatives of persons with mental disorder feel "stigma by association," with 18% admitting that they thought, at times, that the mentally disordered relative would be better off dead (Oestman & Kjellin, 2002). In China, 60% of family members of adults with Schizophrenia stated that stigma had moderate to severe effects on the afflicted person's life, with 26% claiming the same level of effect on the lives of family members (Phillips, Pearson, Li, Xu, & Yang, 2002). Not surprisingly, such effects were perceived to be stronger for patients with more severe levels of pathology and in families with higher levels of negative emotion regarding the member with Schizophrenia; as noted earlier with respect to the United States, they were also stronger in families with higher, rather than lower, levels of education. In recent investigations, stigma was also strongly perceived by caregivers in the African nations of Ethiopia and Nigeria (Ohaeri & Abdullahi, 2001; Shibre et al., 2001), as well as in India (Thara & Srinivasan, 2000; for an overview of mental illness and its stigmatization in Islamic countries, see Al-Issa, 2000).

Another perspective on family stigmatization emerges from turning the generational issues in the other direction. That is, what are the effects on children when a parent has a mental illness, particularly when the parent himself or herself is stigmatized? First, having a parent with a major mental illness is a key risk factor for disorder and impairment in offspring (e.g., Beardslee, Versage, & Gladstone, 1998). The mechanisms underlying this association are varied; they include the potential for genetic mediation, marital disharmony, lack of parental responsiveness, and modeling of emotional dysregulation (Hinshaw, 2004). Second, one key variable underlying the risk may include the difficulties parents have in communicating directly and clearly with their children about the nature of their own mental disorder. Indeed, in the presence of stigma, the predominant parental tendency is concealment and silence (Lefley, 1992; Wahl &

Harman, 1989). Yet, when no information is forthcoming about parental absence or disruption, children will tend to blame themselves, compounding other sources of risk for disorder and dysfunction (Hinshaw, 2005). Thus, a key antidote to stigma is the promotion of family communication to children and adolescents about the mental disorders of parents or close relatives (Beardslee, 2002; Hinshaw, 2004). Such communication not only demystifies the puzzling behaviors but also models openness on the part of parents and opens the door for more adaptive coping.

In sum, with the closure of most institutional facilities in the past half-century, family members have increasingly dealt with both the actual care of relatives with serious mental disorder and the emotional and psychological costs of such care in a stigmatizing society. Findings include a wide and distressing pattern of perceived stigmatization, evident cross-culturally. Lacking from such research, however, are (1) considerations of families dealing with forms of mental disorder beyond the most serious, psychotic variants; (2) a more complete perspective on children who live with mentally disordered parents; and (3) developmental factors in the life of a family that predict adaptive versus maladaptive coping and adjustment.

Mental Health Professionals

It might be assumed that those who work directly with persons with mental disorders would be immune to stigmatizing attitudes and practices, but data reveal otherwise. Such evidence began to be accumulated by pioneers in stigma research (see Nunnally, 1961). Many investigations were performed with attitude scales completed by staff of psychiatric facilities during the 1950s and 1960s; note that nearly all relevant research pertains to staff and professional attitudes regarding adult forms of mental disturbance. Findings included the general result that mental health personnel were somewhat more accepting of mental disorder than members of the general community but that different attitudes of mental health workers, such as authoritarianism and benevolence—the latter signifying a belief in the childlike qualities of "mental patients"—were associated with worse patient outcomes (see Cohen & Struening, 1962; reviewed in Rabkin, 1974). Even as funding and models of care have shifted to community-based rather than institutional settings, a continuing pattern of stereotypic beliefs and stigmatizing attitudes has been noted (see Keane, 1990, 1991; Scott & Philip, 1985). In addition, large surveys reveal that mental health staff of many varieties have continued to perceive a lack of integrated services available for their clientele (Mirabi, Weinman, Magnetti, & Keppler, 1985). Also, Fryer and Cohen (1988) found that

staff of a Veterans Administration facility ascribed a host of negative traits, including apathy, hostility, immaturity, selfishness, and aloofness, to persons branded as psychiatric patients as opposed to general medical patients. As recently as 2002, Mukherjee, Fialho, Wijetunge, Checinski, and Surgenor provided evidence that, in London, half of medical students and physicians surveyed had beliefs in the dangerousness and unpredictability of individuals with Schizophrenia and drug/alcohol problems. The general pattern therefore appears to be one of continuing stigmatization of persons with mental disorder, emanating from some of the very professionals entrusted with their care.

Tellingly, a systematic survey in the United States (Wahl & Harman, 1989) revealed that one of the primary sources of stigmatization perceived by persons with mental illness—and their family members—emanated from demeaning attitudes and low expectations for improvement from professionals providing care. Indeed, among a list of eight potential coping resources for combating stigma, the respondents ranked the act of talking with mental health professionals as the least helpful alternative.

Whereas a great number of those in the mental health professions are genuinely committed to improving their clients' clinical status and helping foster autonomy, the models of training in psychology, psychiatry, and other helping professions often convey a superior attitude, promoting an "us versus them" mentality (Hinshaw & Cicchetti, 2000). In addition, the mental health professions have low status in comparison with other medical subdisciplines—again providing evidence for courtesy stigmatization—and medical professionals have often voiced disparaging attitudes toward clientele with mental disorders (for historical information, see Nunnally, 1961; see also Wahl, 1999). Working with patients who have serious mental disorders can be stressful, particularly with relatively low pay and low status. As a result, staff burnout, use of inappropriate humor, and scapegoating of particularly difficult clients and diagnostic categories occur (Wahl, 1999). In short, mental health professionals may inadvertently foster stigmatization through attitudes of superiority, paternalism, and separation from persons with mental illnesses and through theoretical modes that fundamentally blame parents and family members for mental disorders of children and adolescents.

Summary

The present review has barely scratched the surface of the voluminous research on stigmatization related to mental disorder. Although the general public is more knowledgeable than before about mental illness, fundamentally negative attitudes still abound; these have apparently increased

over the last 50 years. Behavioral research indicates that persons with mental illness are highly prone to receive discrimination. When persons with mental disorders receive stigma, negative influences on future outcomes are likely, even with initial mental symptoms taken into account. Family shame and stigma regarding mental disorder are major issues, with parental blame emanating from professional and scientific perspectives that attribute the etiology of mental illness exclusively to poor parenting. In addition, when parents have mental disorders, the risk of transmission to offspring is compounded by the presence of stigmatization and silence. Finally, at least some mental health professionals themselves are prone to display stigmatizing, patronizing, and sometimes hopeless attitudes regarding the very persons they are serving.

Overall, has stigmatization toward persons with mental illness increased or decreased in recent years? Although some improvements in knowledge and overtly expressed attitudes are apparent, no research has been performed on perceivers' implicit, unconscious biases, which remains a major priority for future investigations. Furthermore, Sartorius (1999) claims that stigma has actually increased in recent times, related to three key factors: (1) increased urbanization, making displays of deviance salient to more of the population; (2) increased educational levels and increased skill demands for technological jobs, rendering educational failure and unemployment related to mental disorder more noticeable; and (3) extensive growth of a middle class in many societies, yielding a tendency toward standardization and conformity of behavioral displays that make nonconforming behavior more visible and disturbing. Together with the increased tendency for the populace to link mental illness with violence and danger (Phelan et al., 2000), this analysis provides caution for those who posit linear reductions in stigmatization with the continued advent of modernization and Westernization.

Beyond the empirical evidence just reviewed, less formal indicators of stigmatization are even more revealing. I therefore expand my coverage to include broader types of evidence for stigma, including indicators in the general culture and language of everyday life; depictions in the public media; discrimination with respect to such areas as housing, employment, and health care coverage; and personal, narrative accounts from individuals with mental illness and their family members.

Broader Evidence in the General Culture for Stigma

The task of searching for general indicators of stigma in relation to mental illness is more difficult than might be

thought. The reason is that widely held attitudes and stances in a given culture are often so pervasive and grounded in everyday life that specific mention of them is hard to find. Goldhagen (1996) noted a parallel problem in his search for anti-Semitic attitudes in Germany during the 1930s, in that the very pervasiveness of such beliefs masked their presence. He quoted an unnamed scholar: "To be an anti-Semite in Hitler's Germany was so commonplace as to go practically unnoticed" (p. 32). Similarly, the stigmatization of mental illness is so deeply embedded in our culture's words, pictures, and practices as to escape easy detection unless a concerted effort is made to uncover such images and to realize that many cultural epithets are, in fact, directed against those with mental illness.

Everyday Language

The very words in common use convey stereotyping and stigmatization about mental illness. If, during the course of an argument about even trivial matters, a person makes a statement that appears out of line with the flow and logic of the discussion, a common response from his or her interaction partner may well be "Are you insane?" Unpopular ideas are commonly dismissed as "crazy" or "nuts"; outlandish plans are branded as "madness." When individuals say or do things that fail to show foresight or forethought, they are all too commonly called "idiots," "imbeciles," or "morons," the formal terms to indicate mental retardation during much of the past century. It is revealing to recognize the extent to which a host of disparaging terms relate to mental disorder: Ideas are "deranged," persons who behave outside the norms are "lunatics," strange behavior is branded as "psycho," and an individual whom one would not want to meet is often a "mental case." The frequency of use of such terms reveals a veritable preoccupation with the rationality and conformity of social partners.

Other linguistic practices are even more graphic. Murderers are "psycho killers," even in popular rock songs. Those who promote strange ideas are "wacked," and facilities for those with mental illness are "loony bins" or "nut houses." This kind of language reveals fear as well as fascination: fear that the affliction could befall the perceiver and fascination with the illicit, perhaps dangerous or bizarre behavior patterns underlying the terms and labels. Children come to use such terms at early ages, signaling the pervasiveness of the cultural disparagement of persons with mental disorders. Indeed, pejorative labels linked to mental illness or mental retardation ("crazy," "retard") are among the initial terms used to castigate socially rejected peers.

Media Depictions

Perhaps the most telling evidence in modern culture related to the stereotyping and stigmatization of mental disturbance is found through analyses of media portrayals of those with mental disorders (Wahl, 1995). Although there are a few recent signs that depictions in public media are beginning to be less disparaging than has been the case for many decades (Wahl, Ward, & Richards, 2002), the pervasiveness of distorted media images is a major issue for anyone concerned with stigma. Nunnally (1961) presented disheartening accounts of media practices in the 1950s, concluding that images from visual media were grossly negative, unflattering, stereotyped, and sensationalistic. Commercials, soap operas, prime-time dramas, advertisements, and newspaper/magazine accounts continue to portray persons with mental illness as deranged, violent, and unpredictable with alarming frequency (Coverdale, Nairn, & Claasen, 2002; Diefenbach, 1997). Most accounts of mental disorder focus on the most extreme variants of mental illness, such as Schizophrenia; descriptions of violence have been almost omnipresent (Shain & Phillips, 1981). Tellingly, television cartoons are quite likely to depict mental illness in characters, and such portrayals are typically stereotyped and pejorative (Wilson et al., 2000). Even when media portrayals do not include stereotyped depictions of violence and utter irrationality, they still often depict incompetence, unemployment, and grossly disturbed affect (Hinshaw, 2006; Nunnally, 1961). The firsthand accounts of persons with mental illness, and their family members, are hardly ever reported. Overall, pervasive and negative media images—replete with ridicule, violence, and disrespect—are a primary vehicle for promoting stigma in the current era.

Discriminatory Policies

A host of discriminatory policies are still in place. Several levels of discrimination can be differentiated: (1) direct discrimination, where, for example, housing is denied based on knowledge of an applicant's mental disorder; (2) structural discrimination, entailing the curtailing of rights of those with mental illness because of policies and the formation of societal barriers; and (3) discrimination via self-stigmatization, a subtle but pernicious form through which an individual's internalized stigma prevents his or her utilizing life opportunities (Angermeyer & Schulze, 2001).

Of great significance is the lack of full parity of insurance coverage for mental, as opposed to physical, illnesses. For one thing, many individuals often do not recognize that behavioral and emotional problems emanate from mental

disorders; this process may be related to general ignorance as well as stigmatization. Yet, even if such recognition exists, stigma may limit help seeking, even among military personnel who are experiencing posttraumatic responses (Hoge et al., 2004). Indeed, this phenomenon is an example of self-stigmatization. Crucially, however, imagine the scenario when recognition and willingness to seek treatment are in place, which itself is a major victory, yet inadequate funding for treatment may still preclude the receipt of treatment. That is, an individual wishing for treatment, or a family seeking intervention for their child, may be able to receive full reimbursement for “physical” illnesses but lower levels of care, often inadequate to the task, for a disabling mental disorder. It is hard to imagine a more blatant form of stigmatization than this, which is clearly a factor in spurring the low service utilization rates for persons and families with mental illnesses (New Freedom Commission, 2003; Wang, Demler, & Kessler, 2002).

As I write this chapter, partial parity legislation is the law of the land, with more stringent bills (e.g., the Senator Paul Wellstone Mental Health Equitable Treatment Act) undergoing congressional debate. Although there would certainly be some cost increases related to such legislation—on the order of 1% a year for premiums—the overall cost of lost productivity related to mental disorder approaches \$100 billion per year, so that parity legislation would almost certainly effect overall savings.

Several other legal issues are salient. Independent housing for persons with mental illness is extremely difficult to find, related in part to the fact that public assistance benefits in several U.S. states are not enough to cover the cost of a monthly rental, much less food and other necessities (Cooper & O’Hara, 2003). In addition, as highlighted earlier, the disclosure of a history of mental disorder greatly limits the availability of even being shown an apartment that has been advertised (Page, 1995). Because housing is a key variable related to self-esteem and productivity (Carling, 1990), this issue remains a major priority.

In terms of employment, although the Americans with Disabilities Act supposedly eliminated discrimination in public and work settings, persons with a history of mental illness know that disclosure of their past can nearly automatically exclude their consideration for various jobs and can lead to loss of status—or even of work itself (Wahl, 1999). Furthermore, the rigorous economic analyses of Marcotte and Wilcox-Goek (2001) showed that each year in the United States, between 5 million and 6 million individuals with mental disorders lose, fail to seek, or cannot find employment as a consequence of their mental illness. As a result, poverty is a common consequence of mental

disorder. Finally, persons with a history of mental illness even have difficulties obtaining a driver’s license, securing voting rights, maintaining child custody, or performing jury service (Corrigan, Markowitz, & Watson, 2004; Wahl, 1999). All of these indicators of discrimination constitute *prima facie* evidence of continuing stigmatization.

Personal and Family Narratives

Powerful accounts of stigma emanate from personal stories of individuals who have been affected by mental disorder and its castigation. Such accounts, however, have typically been discounted and ignored. From a scientific perspective, there are well-documented limitations to case studies, whether written by clinicians or those persons directly affected. How is it known, for example, that the individual described is representative of the population of interest? What about the variables that are not controlled? Second, because persons with mental disorders have been devalued, with their very rationality questioned, a common rejoinder is that no one would be tempted to believe their personal narrative accounts. Indeed, wouldn’t their personal stories be tainted by distorted thinking?

I contend, however, that studying narratives can give a sense of the teller’s personal interpretation of key events, of the variables important to the narrator’s self-definition, and of the relation of events and perceptions to cultural context of the account. Most important, narrative may effectively humanize crucial social issues. Indeed, as noted earlier, when individuals with mental disorders are perceived as subhuman, the most vehement stigmatization is likely to occur. To the extent that narratives can portray the real person behind symptoms, treatments, discrimination, struggles, and triumphs, empathy may be greatly enhanced. Although there are certainly instances in which severe mental disorder may lead to highly irrational thinking and writing, accounts from lucid periods may be highly revealing of both symptoms and social practices.

Until recent years, there have been only sporadic examples of personal accounts and narratives capturing the public imagination sufficiently to motivate change in the mental health system (e.g., Beers, 1945). More recently, however, a number of compelling personal accounts have appeared, and these have opened up the topic of mental illness to large segments of the general populace (e.g., Jamison, 1995; see also the Academy Award-winning film *A Beautiful Mind*).

The increasing numbers of disclosures from individuals with mental illness, as well as their family members, provide poignant testimony to not only the vicissitudes and ravages of mental disorder but also to the pernicious

effects of stigma and the resilience and strength that can emerge from mental illness (e.g., Hinshaw, 2002; Jamison, 1998; Neugeboren, 1997). Recently, Beard and Gillespie (2002) have provided testimonials from many families in which a child has been diagnosed with a mental disorder, revealing considerable stigma. To the extent that such narratives become more accessible, more complete and compelling evidence for stigmatization, as well as strength and courage, can emerge. Personal and family narratives provide rich, firsthand views of the experience of mental disorder and the stigma that frequently accompanies it. They can portray the realities of mental illness as both human and real, supplanting both statistical accounts and stereotypic depictions. Narrative can thus provide the message that stigma is a topic worth discussion and that individuals with mental illness are first and foremost human (for more complete reviews, see Angell, Cooke, & Kovac, 2005; Hinshaw, 2006).

Summary

In short, a host of “everyday” evidence reveals pervasive and often devastating effects of stigmatization on the lives of persons with mental disorders and their family members. Coupled with the empirical research cited, this evidence leaves little doubt that stigma related to mental illness is still a central issue for the research and clinical fields as well as society at large. I next consider the specific ways in which prejudice, discrimination, and stigmatization may reveal themselves across the life span, as well as how key developmental principles can benefit the future investigation of stigma processes.

DEVELOPMENTAL THEMES

Much of the current social psychological and evolutionary psychological work on stigma is developmental, dealing with adult manifestations of stigma processes but failing to take into account either mechanisms related to stigmatization across the life span or key principles from developmental psychopathology that could enrich understanding of the causes and effects of stigma. In this section, I provide coverage of both of these essential points. For elaboration, see Hinshaw (2005), Hinshaw and Cicchetti (2000), and Hinshaw (2006).

Stigma across the Life Span

Here I consider various life stages, in chronological order, and the potential for stigmatization to play a key role in each.

Infancy and Toddlerhood

At first glance, stigma pertaining to disorders of infancy and toddlerhood might not appear to be a major concern. Indeed, infants and toddlers have limited language skills and self-reflective abilities. But stigma processes can be quite intense—and quite important developmentally—when there is the possibility of mental illness in a very young child. Indeed, when the topic is expanded to include the entire family, the potential for diagnosis of mental dysfunction in a child of this age almost always incorporates implicit, if not explicit, blaming of parents. Indeed, as noted earlier, faulty parental socialization practices constituted the key etiologic models for mental illness throughout much of the past century. With ascription for the locus of such problems made explicitly to poor attachment or unresponsive parenting, it is little wonder that parents would be reluctant to seek assessments and diagnoses. Alternatively, the attribution may be made to genetic flaws (e.g., Rutter, 2000), which may convey substantial stigma as well, as the previous discussion has illuminated.

The point is all the more important because of the utter need for accurate screening, diagnosis, and treatment of the earliest child mental disorders, such as Autistic Disorder, other pervasive developmental disorders, very early onset depression, and ADHD. But the general ignorance of the possibility that serious mental disturbances can exist at this age, coupled with the stigma attached to having a young child with mental illness, often serve to delimit early assessment and detection.

Preschool and School-Age Children

During the preschool and school-age years, similar issues are salient, in that ignorance of the existence of mental disorders, shame at admitting their presence, and a lack of treatment options (and funding) all conspire to delimit needed prevention and intervention. Indeed, as noted throughout this chapter, rates of treatment seeking for children with mental disorder are abysmally low in the United States and are undoubtedly even lower elsewhere (e.g., New Freedom Commission on Mental Health, 2003). Compounding the problem is the importance of academic achievement during childhood. The presence of a mental disorder may hamper the child’s ability to focus on school curricula and master educational material (see Hinshaw, 1992, for information on the complex associations among ADHD, aggressive behavior, and underachievement). Under federal law, parents are guaranteed the right to a school-based assessment and, if special needs are documented, appropriate accommodations under the concept of

the “least restrictive alternative” (i.e., that the youngster is placed in settings that are as close as possible to mainstream classrooms). If, however, stigmatization leads to the family’s reluctance to acknowledge a child’s emotional and behavioral difficulties, neither assessments nor accommodations can be implemented. Stigma may therefore limit important life opportunities during years that are crucial for gaining academic skills.

Therapeutic efforts with children nearly always require collateral work with parents, even if systemic intervention with the family is not the treatment of choice. Such work requires careful attention to stigma processes. Crucially, clinicians must become familiar with current scientific literature that has largely debunked prior conceptions of psychogenic, particularly child discipline-related, causation of most childhood mental disorders (e.g., Mash & Barkley, 2003; Phares, 2003). Psychoeducation about the complex array of biological predispositions and life stresses that produce psychopathology may go a long way in limiting blame, recrimination, and self-doubt among parents and family members.

At the same time, it is essential that clinicians do not head to the other extreme and posit reductionistic, biological causal factors as the sole determinants of child mental health issues. Recent research has made it clear that child and family influence in child behavior disorders is reciprocal and transactional in nature (e.g., Hinshaw & Lee, 2003). Even for conditions with substantial heritability, psychosocial influences such as parenting and stressful life events are highly related to outcome in certain subgroups (e.g., Caspi et al., 2002, 2003; Hinshaw et al., 2000; Tully, Arseneault, Caspi, Moffitt, & Morgan, 2004).

The findings from Hinshaw et al. (2000) are noteworthy because they reflect mediator processes in a randomized controlled trial of long-term medication, behavioral, and combination treatments for 579 children with carefully diagnosed ADHD, known as the Multimodal Treatment Study of Children with ADHD (MTA; MTA Cooperative Group, 1999a, 1999b). The important backdrop for this discussion is that behavioral genetic investigations reveal substantial heritability for ADHD, on the order of .7 to .8 (Swanson & Castellanos, 2002). In fact, with such strong genetic liability, it might be believed that parenting cannot be related to outcome. The MTA findings, however, revealed that in the combination treatment, incorporating the multimodal approach of well-delivered medication plus intensive school- and home-based behavioral consultation, the children whose parents showed the strongest improvements in their negative/ineffective discipline styles ended treatment with not just improved but fully normalized rates of disruptive

behavior in their school settings. That is, changes in parental discipline were linked with the superiority of the combination treatment in *normalizing* teacher-reported aggressive and hyperactive behavior; they also served as a mediator variable for comparable improvements in the children’s social skills (Hinshaw et al., 2000). Thus, even for a condition as psychobiologically based as ADHD, socialization processes appear quite related to maintaining and even improving clinical symptomatology and impairment over time (see Cicchetti & Hinshaw, 2002, for detailed accounts of the ability of clinical and prevention trials to yield conceptually rich information on processes and mechanisms of psychopathology). The message for stigma reduction is clear: Although parents do not appear to *cause* ADHD in terms of parenting styles, their socialization practices are essential for determining *outcome and course*.

In other words, clinicians can simultaneously reduce parental blame and foster parental responsibility for children’s mental health. Stigma reduction can be facilitated when families are no longer blamed as the causes of Autistic Disorder, ADHD, learning disorders, and other key childhood conditions. Yet, along with the message that parents are not the causal agents for such disorders, the counterpart communication is equally crucial, namely, that parents and other socialization forces are clearly and centrally responsible for shaping outcome (see also Campbell, 2002). In addition, with respect to other conditions for which parental negativity and dysfunctional parenting practices are more causally linked to symptomatology (e.g., conduct problems), stigma may delimit parental treatment seeking; hence, responsive clinicians must simultaneously work to improve family discipline and communication and to reduce the self-blame that parents may be experiencing.

Adolescence

Adolescence is noted as a period in which identity consolidation and the gradual gaining of autonomy occur (see Feldman & Elliott, 1990). Mental illnesses with onset, or continued presence, during adolescence may be particularly devastating for the solidification of identity, independence, and the sense of fitting in with peers or “belonging” in the regular world (Hinshaw, 2005). Indeed, the devastating impact of a mood disorder, the disorganization and fragmentation that characterize psychosis, and the paralysis of psychological and even physical development that can accompany Obsessive-Compulsive Disorder and severe eating disorders are all highly likely to emerge during the adolescent years; they may shape self-perceptions and the potential for independent functioning for years to

come. When self-stigmatization is added to the mix—that is, when the adolescent is ashamed to admit that he or she suffers from a mental disorder—the chances for intact self-esteem and for maintaining a sense of personal agency are further compromised.

Furthermore, if the illness is severe and hospitalization is required, the kinds of institutional practices of past years, which featured dehumanizing settings, punitive procedures, and major restrictions on autonomy, may have far-reaching effects on an individual's self-image (Hinshaw, 2002). Indeed, essential for destigmatization is that mental health staff and therapists show respect for the integrity and autonomy of their clientele, particularly those who are adolescents (see earlier section on mental health professionals). Improved personnel selection, training, and pay scales can all play important roles in this effort.

I point out that social policies currently in place in the United States convey both stigmatizing and fragmenting messages for families of adolescents. In fact, parents of adolescents with serious behavioral or mood disturbances are sometimes able to procure needed day treatment or residential services only if they give up custody of their offspring (see Hinshaw, 2006). This practice reflects both the critical shortage of needed facilities for children and adolescents with severe problem behavior and the inherently stigmatizing messages regarding family unity embedded in current policy. Essential federal legislation, such as the Keeping Families Together Act under consideration by the U.S. Congress, could help to stop this forced practice of family dissolution to obtain needed services.

Adulthood

During adulthood, many persons with mental disorders utilize a core strategy of secrecy and concealment (see Link, 1987). Shame, fear of losing employment or housing, and the potential reality of curtailed health insurance if a history of mental disorder is divulged are all potential motivators for such a stance. This strategy may compound the loneliness, isolation, and lack of social support that are frequent accompaniments to many forms of mental disorder, perpetuating a vicious cycle of despair, silence, and impairment. I am not advocating that individuals with a history of mental illness disclose their personal narratives indiscriminately. Indeed, given the climate of stigma, such a strategy could well be counterproductive. Rather, because of the potential consequences of a life filled with silence, shame, and isolation, opportunities for disclosure and support should be utilized to the greatest extent possible (Hinshaw, 2002).

When adults with mental disorders are also parents, the impact of stigma can be particularly devastating for the

family. Specifically, children are highly likely to internalize blame for their parents' conditions if they do not understand the absences, erratic behavior, and deprivations they may experience in terms that they can understand. To the extent that youngsters begin to comprehend that such experiences are outside their personal control, they can be freed from potentially devastating guilt and self-blame. Parental mental illness is clearly a risk factor for disordered functioning in children, as argued earlier, but stigmatization may compound the problems exponentially, to the extent that the family is engulfed in shame and silence and offspring do not receive assurance and needed information (Hinshaw, 2004). Finding ways to encourage productive discussion among family members is a needed step, requiring a form of family intervention that demands honesty, frank disclosure, and a willingness to receive input from multiple sources of support (Beardslee, 2002).

Another relevant issue is a pervasive social attitude toward mental illness, namely, that it permeates all aspects of the person's being. This perspective may foster the individual's becoming identified with the disorder. In other words, because having a mental disorder is associated with the person's entire being, the individual may begin to view himself or herself as "a schizophrenic," "a manic depressive," or "an obsessive-compulsive." This practice is all too often perpetuated by professionals who link the individual with his or her disorder. The underlying humanity of the person in question is likely to be buried beneath the diagnostic label, which connotes weakness, deviance, permanence, and a sense of fundamental flaw. Individuals with mental illnesses are first and foremost human, a view that may get lost unless the diagnostic label is applied to the condition rather than the entire person (American Psychiatric Association, 2000; Hinshaw & Cicchetti, 2000). Because stigma processes are by definition pervasive and globalizing, the struggle to retain the individual's identity and humanity in the face of a mental illness may be a difficult one.

Finally, I note in passing that elderly persons with mental illnesses must fight the dual stigma of being old (and often disenfranchised financially as well as isolated from their family) and mentally disordered. Differential diagnostic issues related to cognitive decline versus mental disorder, or their comorbidity, are paramount. Yet the isolation and stigma that pertain to decrements in psychological and mental functioning for elderly persons often curtail any efforts to obtain diagnostic clarity.

Summary

Across the life span, stigma has important implications for the attainment of competence, the development of a sense

of self, the ability to gain independence and a sense of personal agency, the ability to receive social support and acceptance, and the struggle for families to maintain services for their offspring with mental disorders. The pain and impairments that emanate from mental disorders are often quite severe; when stigma and discrimination are included, chances for life success are markedly diminished (Hinshaw, 2006; U.S. Department of Health and Human Services, 1999). A life span perspective is essential to understand the pervasiveness of the consequences of stigma for multiple aspects of individual and family functioning.

Developmental Psychopathology Issues Related to Stigma

The enterprise of developmental psychopathology, the field that explicitly links normal and atypical development and that comprises the overarching topic of this entire volume (see also Rutter & Sroufe, 2000), embraces a number of core principles. I note several of the most salient of these and integrate them with the many considerations already raised regarding stigma in relation to mental disorder.

Continuities and Boundaries between Normal and Atypical

A core tenet of developmental psychopathology is that atypical, pathological behavior patterns represent aberrations in pathways that otherwise lead to normative development. That is, mental disorders are not fixed, static entities but rather the end points of developmental processes marked by flux and change (Cicchetti, 1993; Hinshaw, 1994). Indeed, they represent fluid states that typically alternate with periods of more normative functioning, best understood as disruptions in developmental processes that typically yield adaptation. Thus, persons with mental disorders are not fundamentally different, in type, from other humans, even though they may have genetic propensities for emotional and behavioral disturbances that render them susceptible to the influence of stressful environments ranging from prenatal and familial settings to wider cultural socialization contexts.

Although it is possible that certain mental disorders are best understood as taxa—that is, as categorical entities discrete from the norm—most mental illnesses appear to be far more continuous in nature, presenting as extremes of distributions of underlying behavioral, cognitive, and emotional statuses. (In actuality, categories of mental disturbance can be simultaneously continuous and categorical, depending on which criteria are used to examine their fea-

tures, in the same way that light can represent both waves and photons; for a lucid discussion, see Pickles & Angold, 2003.) It is therefore mistaken to view mental illness as qualitatively distinct from normative processes. The upshot for stigmatization is that views of mental disorder as constituting qualitatively different, flawed, and inferior kinds of functioning are misguided (see Haslam & Ernst, 2002, for a critique of essentialist ideas about mental illness). The fundamental humanity of individuals with mental illnesses must be emphasized, potentially leading to increases in compassion and hope for amelioration of their course.

Ecological Models

Developmental psychopathology emphasizes the linkages between individuals and their environments, such that pathology and coping are hypothesized to reside in the interface between persons and settings (Bronfenbrenner, 1977). Thus, pathology does not reside in the individual per se or in the environment per se but rather in the “fit” between them. Psychopathology constitutes an imbalance between personal resources and environmental supports.

Intriguingly, stigma itself is also a relational construct, constituting a mark of degradation made by society related to membership in a group believed to be evil, flawed, or contagious. For children and adolescents, stigma processes occur in families, schools, and communities; thus, the concept of fit between individual and setting is crucial to the diagnosis of the child as mentally disturbed. Adults, as well, are judged by societal standards of appropriate deportment in decisions regarding mental illness. Although the impairments related to serious mental disorder are undoubted, it is also important to understand that changing environmental standards may render certain behavioral tendencies more or less adaptive. Deviancies and flaws in one cultural context may well be adaptive in others. Again, with the adoption of essentialist beliefs that mental illness is a fixed, discrete type of behavior rather than a product of fit between person and environment (Haslam & Ernst, 2002), stigma may be intensified. Fostering tolerance and acceptance of deviant behavior patterns, so long as they are not threatening to others, will require adapting contexts and environments (i.e., school, home, workplace) to maximize the potential for productive behavior.

Reciprocal Determinism and Transaction

In developmental psychopathology models, mental disorder results from interactive linkages between individual-level constructs (such as genotypes and temperament), relational variables (including attachment and parenting styles), and wider systems influences (school or neighborhood settings)

in shaping typical as well as atypical development. Such interactive influences unfold over time and across development, reflecting the construct of *transaction* (Sameroff & MacKenzie, 2003). The upshot of such transactional perspectives for stigma is that preconditions for psychopathology are modifiable by environmental circumstances. For example, in groundbreaking work, Caspi and colleagues have recently found that both genotypes and crucial environmental circumstances work interactively to yield risk for psychopathology. Specifically, polymorphisms of the monoamine oxidase gene are shaped differentially by abusive encounters in childhood to yield risk for antisocial behavior (Caspi et al., 2002), and different alleles of the serotonin transporter gene are affected in different ways by negative life events to produce clinical-range depression (Caspi et al., 2003). Once again, psychopathology is not a fixed product of biology or environment but a product of interactive processes.

With such dynamic models in mind, it is difficult to make reductionistic arguments that mental disorder is a sole product of genes or of dysfunctional environments. Implications for stigma are important. That is, stigmatization of families is likely to occur when parenting is viewed as the primary cause of mental illness, and derogation and punishment of the individual are strong possibilities when deviant genetic makeup is indicated as the primary determinant of mental disorder (e.g., Mehta & Farina, 1997). On the other hand, understanding the inherently transactional nature of mental disorder should help to take blame away from both parenting styles and flawed individual constitutions as the exclusive loci of mental disturbance. Transactional models are not intuitively obvious, especially in a culture that continues to value simplistic sound bites as the predominant mode of communicating complex biological, social, cultural, and even political messages. Yet promoting the notions of vulnerability, life stress, interaction, and transaction may help to reduce the stigmatization associated with extremes of exclusively environmental or exclusively biological perspectives. Such promotion may help to shape lay views of psychopathology as reflecting combinations of internal preconditions and external stressors, working together across time.

Resilience

The pain and impairment related to mental disorder are undoubted, but it is also the case that the symptoms of many mental disorders wax and wane over time, that periods of relatively normal functioning are prevalent in many persons with mental disturbances, and that many such individ-

uals can make unexpectedly good life adjustments. In other words, resilience is a real possibility for individuals with mental illness (Hinshaw, 2002). Resilience is defined as the attainment of positive outcomes in the presence of risk for maladjustment (Luthar, Cicchetti, & Becker, 2000; Masten & Coatsworth, 1998) and provides a needed antidote to views of mental disorder based solely on pathology. Involving both individual characteristics (humor, intelligence, persistence, certain temperamental traits) and familial and community supports (presence of mentors or extrafamilial supports in childhood, healthy partners in adulthood), it is a concept that is important to consider with respect to mental disturbance. That is, when the general public comes to understand that mental illness is not inevitably associated with despair and degradation and that a range of healthy outcomes is possible in persons who have experienced mental disorder, stigmatizing attitudes may change. Indeed, views of mental disturbance that show its malleability rather than chronicity should facilitate stigma reduction (see Jones et al., 1984).

It would be a mistake, however, to apply “Pollyanna” approaches to depictions of mental illness. Indeed, many reform efforts have foundered on the shores of unrealistic, overly optimistic views of the amenability of serious mental illness to community treatments (see Grob, 1994). The promotion of realistic, rather than oversimplified or sensationalistic, portrayals of mental disorder is urgently needed at the level of public media. There are signs that more positive images of mental disorder have made their way into cultural consciousness (e.g., see Wahl et al., 2002). Extending these images to children and adolescents with Autism, ADHD, learning disorders, conduct problems, depression, and other developmental disorders, as well as adults with a variety of mental illnesses, is a needed step to overcome stigma. When it is realized that individuals with serious forms of mental illness can attend school and learn as children, can be sensitive and loving parents as adults, and can maintain their integrity and retain a strong sense of meaning in life (see Hinshaw, 2002), then stigma reduction will have begun in earnest. The more human and realistic the portrayals, the stronger the likelihood of stigma reduction.

INTEGRATIVE MODEL OF THE STIGMATIZATION OF MENTAL ILLNESS

I now attempt a brief synthesis of the many concepts reviewed above about the stigma of mental illness. This model features principles from social, evolutionary, and

developmental psychology as well as sociology and developmental psychopathology, with particular emphasis on concepts linked to threat (Stangor & Crandall, 2000; see also Blasovich, Mendes, Hunter, & Lickel, 2000). (I do not have space to consider another variant of such models, namely identity threat theory, with regard to responses of those stigmatized; see Major & O'Brien, 2005.) Note that any accurate portrayal of stigma must acknowledge its overdetermined nature, with stigma processes operating at the levels of individuals, families, communities, and broader social and political contexts (e.g., Hinshaw, 2006; Link & Phelan, 2001). Attempting to find which level of analysis is primary is destined to be futile, as all levels interact and transact. In other words, stigma is a joint function of individual psychology (and even naturally selected proclivities), forces related to dyadic and larger group social interactions, and cultural and economic forces at work in a given society. All too little is known about its emergence across development, constituting a key research question for the future.

First, symptoms of the most severe forms of mental illness are threatening to social perceivers. Some of this threat may not require much in the way of cognitive mediation on the part of perceivers; for instance, psychotic behavior, with its inherently irrational and unpredictable nature, may yield threat to personal space or physical integrity. It may also give the perceiver a sense of the fragility of control over his or her own mental life. Some of the symptoms may, at a primitive level, convey a sense of potential contagion (see Kurzban & Leary, 2001); they may also disrupt the perceiver's fundamental foundation of a stable, predictable world and thus stir fears of mortality. Thus, the threat value of such symptoms is multifaceted.

Despite real variations across history and across cultures regarding response to such symptoms (see Littlewood, 1998), these patterns of behavior have tended to evoke, fairly consistently and even automatically, emotional responses of anger (over the violations of social contracts and reciprocation) and revulsion (over the fear of contamination related to grossly disordered behavior and disheveled appearance). Such responses are expectable from an evolutionary perspective on the development of automatic exclusion modules (Fishbein, 2002; Kurzban & Leary, 2001). In addition, the very label of "mental illness" has taken on a variety of meanings (as have many other poorly understood diseases throughout history; see Sontag, 1978/1989), including depravity, weakness, filth, and loss of control. Thus, even mental disorders that are not as inherently threatening as psychotic-level variants carry a

large amount of baggage to social perceivers. Finally, although mental illness does not usually invoke the type of social reactions reserved for nationalistic, racial, or "tribal" differences—involving punitive, exploitive responses (Kurzban & Leary, 2001)—when persons with mental disorder are specifically highlighted as threats to the survival of a nation's viability (as in the case of the heightened eugenics movements in the United Kingdom and United States early in the past century and of Hitler's pointing to persons with mental illness and mental retardation as threats to the Aryan race), then sterilization and even genocide are expectable results.

Persons with mental disorder therefore invoke both real threats to perceivers' expectations of social reciprocity or worries about health status and symbolic threats to their sense of rationality and order in the world. Perceptions of the unpredictability, peril, and chronicity of the disturbance serve to fuel such threat (Jones et al., 1984). Symbolic threat is particularly salient, as the irrational, out-of-control nature of the symptom patterns may elicit fears in perceivers with respect to their own abilities to maintain behavioral and emotional control. Such threats to self-integrity, combined with anxiety raised about stability and even mortality, play an important role in the extremity of avoidance, shunning, and castigation of persons with mental disorder. Note that it is unclear precisely when these responses emerge during individual development; work on this topic should be a priority.

Stangor and Crandall (2000) posit three stages to threat reactions: (1) the initial phase of real or symbolic threat; (2) the subsequent deployment of cognitive distortions and stereotypes to exaggerate differences with the outgroup, serving as a breeding ground for prejudice; and (3) the amplification of such distorted perceptions through societal communication (e.g., mass media) and the invocation of system justification (i.e., blaming the victim) to promote the view that it is not social inequity but rather weakness or deviance on the part of the stigmatized individual that is to blame. In the second and third stages, when the individual in question comes to be viewed as less than human—perhaps because of perceivers' fears of losing their own rationality and reason—then the most harsh, extreme, and even lethal responses will be justified.

One of the hopes of recent decades has been that when mental illness is finally seen from a naturalistic, medical model perspective rather than as a volitional, morally depraved set of behaviors, stigmatization would markedly decrease. As I have highlighted, however, despite some value in viewing mental illness as biologically based rather than

denoting personal culpability (Martin et al., 2000), an exclusive focus on genetic, biological models of the locus of mental illness may actually increase punitive social responses (Dietrich et al., 2004; Mehta & Farina, 1997; Read & Harre, 2001). Factors other than attributions are clearly at play in this regard. Indeed, the threat value of disturbed behavior, its media-promoted association with violence and danger, and general cultural norms regarding the assumption of personal responsibility for behavior and emotion all predispose perceivers to shun and stigmatize those with mental disturbance well before attributions to biological loci are even invoked (Haslam, 2005). Even more, an exclusively biomedical ascription may foster a view of the individual as tainted and flawed, leading to dehumanization and even elimination.

What of the effects of stigmatization on those experiencing mental disorder themselves, termed self-stigmatization by Corrigan and Watson (2002)? Crucially, and unlike ethnic characteristics or physical disabilities, a history of experiencing mental disorder usually exemplifies a concealable mark (unless the individual is floridly symptomatic), meaning that the individual faces the dilemma of whether to reveal such a history to social partners. Considerable anxiety, related to the potential for rejection, is likely with such a concealable stigma. Furthermore, as elaborated by Smart and Wegner (2000), attempts to suppress symptoms and relevant history require great mental effort and are thus likely to be peppered with intrusive thoughts about the concealed attribute in question, in addition to high levels of cognitive and physiological activation. Thus, stigmatization of mental disorder yields intense consequences for those who must contend with its effects on a day-to-day basis. Far greater understanding is required of the kinds of coping strategies utilized by persons with mental disorder in contending with prejudice and stigma, particularly in children and adolescents. Indeed, as emphasized by Wahl (2002), almost nothing is known about the personal experiences of youth with mental disorders.

In closing, I note two key points. First, stigma exists only when social and political power backs the views of the majority over those of the stigmatized outgroup (Link & Phelan, 2001). In other words, individual differences alone do not fuel stigma; only when the traits or attributes in question are officially devalued do prejudice and stigmatization occur. Thus, full consideration of stigma must include structural aspects of social power and the predominant culture's view of what is acceptable in terms of behavioral display (see also Corrigan, 2004). Second, despite the automatic nature of many forms of stereotyping and stigmatization, individuals can and do have the ability

to overcome unconscious, automatic processing of social information through effortful control (Devine, 1989). Thus, the translation of automatic schema and stereotyping into prejudicial attitudes and discrimination is not inevitable, particularly if active, conscious efforts are fostered and reinforced. Thus, despite the perniciousness and pervasiveness of the stigmatization of mental disorder, the situation can change, at both individual and structural levels.

KEY RESEARCH DIRECTIONS

Despite the great volume of research on stigma and stigma processes in recent decades, the vast majority of such work has concerned racial and ethnic prejudice. A host of key questions remain to be addressed regarding the applicability of such models and views to the stigmatization of mental illness. I highlight several of the most salient of these in the current section.

Measurement and Appraisal of Stigma

This is a huge research area, dealing with such issues as basic definitions of stigma (and the related constructs of stereotyping, prejudice, and discrimination) in relation to mental disorder, attitude-behavior distinctions, and the explicit versus implicit nature of stigmatizing attitudes. For a recent, authoritative review, see Link, Yang, Phelan, and Collins (2004).

Defining Stereotyping, Prejudice, Discrimination, and Stigmatization in Relation to Mental Disorder

Too often, investigators do not make clear distinctions among these terms and processes. For example, much of the research reportedly dealing with the stigmatization of mental disorder utilizes surveys of cognitions or attitudes as the chief, or only, measurement tool. Other investigators infer the presence of stigma from a behavioral indicator of discrimination alone. As highlighted earlier, stigmatization should incorporate more than the invocation of stereotypes, the harboring of negative attitudes, or a single act of discrimination. That is, when individuals are stigmatized, they often carry the degradation of the group to which they belong; subsequent interactions are typically strained. A propensity for self-fulfilling prophecies exists, along with the crystallization of castigating attitudes and a propensity for internalization of the devalued mark on the part of those who are so castigated.

Although no single investigation can incorporate all such aspects of stigmatization, inclusion of a few items signifying negative attitudes on a questionnaire is not suffi-

cient to constitute evidence for stigmatization. Optimal research should include, when possible, at least some of the key dimensions of Jones and colleagues (1984)—concealability, course/chronicity, disruptiveness, aesthetics, peril/danger, and origin—in terms of defining stigmatized attributes. It should also consider examination of the potential impact of devaluation on the victim himself or herself, over and above the documentation of negative attitudes and behaviors on the part of perceivers. Documenting reciprocal processes of influence, both attitudinal and behavioral, is also a priority in order to elucidate the cyclic nature of stigmatization and its effects across time. When stigma is characterized solely in terms of isolated negative attitudes or a single act of behavioral exclusion, essential components of this crucial construct may get overlooked. If the database in the field comprises such a thin line of evidence, the contention that mental disorders are stigmatized may come to be perceived as based on trivial evidence, potentially leading to counterreactions (e.g., “Stigma doesn’t really exist”). The burden is on the next generation of investigators to ensure that documentation of stigmatization is as complete as possible.

Linking Attitudes and Behaviors in Relation to Stigmatization

Attitudes and beliefs on the part of perceivers do not translate automatically or directly into behavioral responses (see, e.g., Azjen, & Fishbein, 1980). In other words, negative attitudes may not always yield behavioral rejection, and supposedly positive attitudes may be followed by harsh behavioral responses. Several points are salient with respect to this distinction.

First, to make an obvious point but one that is underappreciated in actual practice, attitude measures may be subject to social desirability as a key determinant of responses. That is, research participants may express kind or benevolent attitudes toward those with mental disorder on their questionnaire responses chiefly because they do not want to appear callous or prejudiced on paper and because social norms have tended, over time, to proscribe derogation of disadvantaged individuals. The work of Link and Cullen (1983) was instrumental in showing that, when primed by a stimulus indicating that a person had a history of mental hospitalization, respondents displayed social desirability in their response tendencies. Specifically, when asked to provide “their own” opinions, respondents provided a more lenient view than when asked to indicate what “most people” would say. Investigators would do well to consider strongly the types of response biases, particularly social desirability, that may taint overt attitude surveys.

Second, measures of attitudes of the general public need to utilize the types of large and representative samples evident in many early studies (see reviews of Rabkin, 1972, 1974). Convenience samples of undergraduates are usually less than ideal in terms of representing the age, educational, and social class levels of the population. The external validity, or generalizability, of both attitude and behavioral research is dependent on the collection of data from broadly representative samples of participants.

Third, in the domain of racial attitudes, it has been found that placing good-bad evaluative adjectives on the same, bipolar, semantic-differential scales tends to yield evidence of no differences in evaluation of Blacks versus Whites. For example, respondents tend to rate Blacks and Whites at the same point of the “lazy-ambitious” continuum. When items endorsing positive adjectives are separated from those pertaining to negative adjectives, however, an interesting pattern emerges: Respondents tend to rate Blacks and Whites equally negatively (e.g., equally “lazy”) but rate Whites more positively (e.g., more “ambitious”). Thus, a variety of positive versus negative qualities and attributes should be included in attitude scales. Furthermore, in the area of mental disorder, Brockman, D’Arcy, and Edmonds (1979) found that questionnaires with fixed, objective response formats tended to yield weaker evidence for derogation and stigmatization than did those requesting open-ended responses, with the latter presumably allowing for freer answers that were not suggested by multiple-choice items or other preselected formats. Investigators in the area of stigma and mental disorder would do well to include narrative response formats, in which respondents are asked to provide open-ended descriptions of their attitudes and beliefs.

Fourth, a major problem in reviewing research on public conceptions of mental disorder is that attitude measures across different investigations and across time are quite difficult to compare. Indeed, on what basis can one assert with confidence that public attitudes have either improved or worsened across a given time period? Investigations in which respondents directly compare individuals with mental disorder to those with other forms of disability or outgroup status are often far more informative. In fact, studies forcing such explicit contrasts have shown that mental disorder is typically one of the least preferred and most rejected among all categories under consideration (e.g., Albrecht et al., 1982; Tringo, 1970). Thus, forced comparisons may be a valuable research strategy, in that they afford appraisal of the castigation of mental disorder relative to other conditions at a given point in time.

Fifth, I highlighted earlier that behavioral research reveals high levels of rejection and discrimination against persons with mental disorder (e.g., Page, 1995). A basic disconnection, however, still exists between most investigations of attitudes and those focused on appraising behavioral indicators. For example, it is nearly impossible to come up with an example of a study in which respondents in behavioral, interactional research—that is, those in which participants interact directly with a person labeled mentally disordered—have also been asked to provide responses on general attitudinal measures toward mental disorder. Admittedly, giving attitude or social distance measures related to mental illness to respondents who are about to interact with persons suspected of having mental disorders could taint or prime the experimental manipulations, if done without forethought. Yet, it would be a significant advance in knowledge to see just what behavioral tendencies and responses emerged from those research participants whose attitudinal responses had also been recorded.

Implicit versus Explicit Expression of Prejudice and Stigma

Many investigators who study ethnic and racial prejudice have come to the conclusion that overt measures of attitude and acceptance fail to tap underlying, implicit attitudes and biases, those that are the most likely to be exhibited in current times, when it is no longer socially acceptable to express overtly prejudicial attitudes. As discussed earlier, the concepts of symbolic racism and aversive racism have come to the fore, signifying forms of racist belief systems that are not commonly expressed on overt questionnaires but that may be revealed through such substitute means as favoring of the Protestant work ethic or strong belief in meritocracy. Needed, therefore, are measurement tools that transcend the overt expression of prejudice.

A key advance in research on prejudice and bias is found in the development of instruments designed to tap covert, or implicit, attitudes, defined as those that exist without the conscious knowledge of the respondent. A major example of such a measure is the Implicit Association Test (see Greenwald et al., 2003). Here, the outcome measure is response latency, or reaction time, as participants associate pairs of concepts with the stimulus of interest. For example, to appraise implicit attitudes toward old versus young people, investigators have respondents view a picture of an old and a young face on a computer screen. From a pair of adjectives (e.g., “old” versus “young,” “good” versus “bad”), respondents indicate the one that best describes the picture. Two sets of adjective pairs are subsequently presented, each of which crosses the age-related and valence-

related descriptors. Unconscious or implicit bias toward elderly faces would be revealed by a quicker latency to the pair “old or bad” than to “old or good”; similarly, bias in favor of younger faces would be signaled by faster latencies to “young or good” than to “young or bad.” In fact, many individuals who profess no age-related bias on explicit response measures show just such implicit biases. Measuring implicit attitudes provides a unique window on the types of responses biases that exist below individuals’ usual levels of awareness.

A key question is whether such a paradigm can be applied to the area of mental disorder. Initial forays are occurring in relation to certain behavioral characteristics. For example, the careful work of Teachman, Gaspinski, Brownell, Rawlins, and Jeyeran (2003) reveals that antifat bias exists at implicit but not explicit levels (for examples of the use of implicit associations in clinical treatment research related to reductions of fears and anxieties, see Teachman, Gregg, & Woody, 2001; Teachman & Woody, 2003). The objective is to circumvent the common problems embedded in explicit means of appraising prejudice: social desirability and a lack of self-awareness of deeply conditioned, underlying response proclivities. Although it is unclear whether such implicit measures actually tap underlying bias versus the salience of cultural stereotypes in the perceiver’s mind, knowing of individual preferences below the level of conscious awareness is important in a full account of stigmatization.

What if mental disorders are the objects of implicit bias? Although troubling, I note that such findings would not imply that such automatic forms of prejudice are immutable. In fact, in the field of racial and ethnic prejudice, it has been shown that individuals who evidence unconscious, implicit antipathy can still make strides—via intentional, planned, effortful means or through repeated exposure to counterstereotypic images—to overcome such biases (e.g., Dasgupta & Greenwald, 2001; Devine, 1989). Indeed, as just noted, it may be the case that some measures of implicit bias detect the amount of exposure one has to certain stimuli in positive or negative contexts but that they do not inevitably portend discriminatory practices. Overall, a key priority for research is to link explicit attitudes, implicit attitudes, and actual behavioral responses toward individuals with mental illness.

Issues Regarding the Independent Variable of Mental Disorder

What is actually stigmatized in the realm of mental illness: the symptoms themselves, particular diagnostic entities,

the general labels of “mental illness” or “ex-mental patient,” or the associations commonly made to such terms? Whereas evidence exists that all of these may be the focus of stereotypes, prejudice, discrimination, and stigmatization, the lesson for researchers is that the independent variable—that is, the construct that is the potential subject of such castigation—must be specified with precision.

Much early research on stigma of mental disorder dealt with the presentation of vignettes of various forms of mental disturbance to participants from the general public to determine whether such descriptions would be recognized as mental disorders and how much social distance would be desired in relation to an individual displaying such symptoms (see Rabkin, 1972). Although evidence now exists that greater segments of the general public recognize several different forms of symptomatology as falling under the rubric of mental disorder than was the case some decades ago, such recognition is far from universal. Furthermore, a key question remains as to whether such “accuracy” in recognition is associated with more favorable attitudes, including decreased social distance (see Link et al., 1999).

A key point from such research is that behavioral depictions of symptoms are more salient triggers of negative attitudes and stigmatization than is the label of mental illness (or “ex-mental patient”) per se, when both types of stimuli are presented to research participants (see Link et al., 1987). Yet, recall that there are key exceptions to this general conclusion. That is, when *normal* levels of behavior are branded as related to mental illness, prejudice and stigmatization are now quite likely to occur, as is the case when labels are presented without any accompanying behavioral symptoms. Furthermore, when a given respondent carries in mind a general association between mental disorder and risk for *dangerousness or violence*, the label propels a strong trigger for stigmatizing attitudes, even when the behaviors associated with mental illness are presented simultaneously (Link et al., 1987). (The flip side of this finding is that if individuals do not hold in mind an association between the label of mental disorder and violence, presentation of the label actually leads to benign attitudes. Hence, the linkage of mental disorder with violence is a key aspect of prejudice and stigma.) Thus, labels *do* matter, and investigations of the effects of diagnoses or labels are still extremely viable as independent variables for future research efforts (see Link, Cullen, Struening, Shrout, & Dohrenwend, 1989, for expert presentation of a modified labeling theory in relation to mental illness).

A great diversity of mental aberrations exist (see American Psychiatric Association, 2000), belying the conception of an overall construct or label of mental illness that is

homogeneous or uniform. Indeed, considering mental disorder to be undifferentiated is not only ill-informed but also potentially stereotypic and stigmatizing in and of itself, given its implicit assumption that people with mental illnesses are all the same. Recognition of the great differences in symptomatology and impairment across the many forms of mental disturbance has led investigators of recent large-scale surveys of public attitudes, both in the United States and abroad, to make careful distinctions among various forms of mental disorder. Findings of such research clearly reveal that the different categories of mental illness are associated with unique profiles of misinformation and stigmatization, even though all forms continue to receive at least some degree of pejorative beliefs and attitudes (e.g., Crisp et al., 2000; Link et al., 1999; A. H. Thompson et al., 2002). Overall, investigators should prioritize the distinction between different types of mental illnesses as the independent variable for most studies that they plan, unless, of course, the generic label of mental disorder or mental illness is the explicit research focus.

Three corollary issues emanate from this general point. First, the chronicity or permanence of a stigmatizing condition is quite likely to be related to negative perceptions of that condition (see Jones et al., 1984). Thus, to the extent that mental disorder is believed to be a chronic pattern of behavioral dysregulation, with little or no chance of cure or rehabilitation, harshly stigmatizing responses are expectable. I point out that such stereotypes continue to exist even among scientists and clinicians. For example, official accounts of mental disorders such as Schizophrenia have repeatedly emphasized its extreme likelihood of being a permanent condition (see Neale & Oltmanns, 1980). Yet, increasing evidence attests to the fact that Schizophrenia is not chronically deteriorating in all, or even a majority of cases. It is essential that such information be explicitly imparted to the general public. Indeed, the term Schizophrenia continues to retain a metaphoric linkage with despair, hopelessness, and devaluation (Finzen & Hoffman-Richter, 1999), and its serious impairments are often associated in the mind of the public as representing all forms of mental disturbance. In short, the specificity of depictions of mental disorder should be emphasized, along with accurate information that may break down common stereotypes.

Second, viewing mental disorder in its specific, variegated forms rather than as a global, amorphous entity prompts consideration of the crucial point that many forms of mental disturbance are less severe, and less inherently threatening at a behavioral level, than the typically investigated conditions of Schizophrenia and other psychotic-level disorders. Yet, far too little is known

about the responses of the general public, family members, mental health professionals, and patients themselves with respect to these more common but less severe forms of mental disturbance. A research priority is to extend work on prejudice, discrimination, and stigmatization to the full range of mental disorders.

Third, when considering the depictions of mental disorder in typical research investigations, mental illness is almost always presented in terms of written vignettes that describe various symptom patterns. Alternatively, the manipulation may relate to the presence or absence of the label of mental illness or ex-mental patient. Yet, direct confrontation of the behavioral and emotional patterns would be far more powerful stimuli than written accounts or verbal labels. It would be extremely worthwhile for investigators to consider research paradigms in which symptoms of mental disorder are presented in videotaped formats, or even, in the near future, via virtual reality simulations. Such depictions may be far more likely to incur real, rather than artificial, encounters with the manifestations of mental disorder, opening the door for more generalizable and viable research. Indeed, virtual reality simulations might yield the side benefit of enhancing empathy for the difficult experiences associated with mental disorder, if presented with appropriate framing and contextualization.

Overall, investigators need to exert care and thought when depicting the independent variable of mental disorder in research on stigma. The presentation of overly inclusive, global, and vague accounts will serve to cloud interpretations of stigmatizing responses and may fuel stereotypes of the notion that all mental disorder is chronic and irremediable. Furthermore, the types of paper-and-pencil accounts of mental disorder in many forms of attitude research may fail to engender the kinds of castigating, stigmatizing responses that are essential to document.

Attributional Analysis of Stigmatizing Responses to Mental Disorder

Attribution research has been an important tool for understanding behavioral and emotional responses of individuals to unexpected and unpredictable events, particularly those that are negative in nature (e.g., Heider, 1958; Weiner, 1985). A key tenet of this work regarding the stigmatization of mental disorder is that attributions of personal control and responsibility for devalued conditions should increase the blame, punishment, and castigation they receive, whereas ascriptions to noncontrollable causes should foster sympathy. Thus, to the extent that mental illness is

believed to be volitional and under the personal control of the individual in question, harsh reactions and stigmatizing responses would be expectable responses. Along this line, the general public tends to believe that mental disorders are personally controllable and that individuals with mental illnesses are more responsible for their conditions than are those with physical disorders (Weiner et al., 1988). It is not surprising, then, that mental disorders are highly stigmatized.

As I have emphasized repeatedly, however, although tendencies to ascribe mental illness to biological roots rather than personal flaws or other controllable circumstances may help to reduce blame and social distance (Martin et al., 2000), attributing mental disorder exclusively to noncontrollable biomedical or genetic causal factors does not appear to reduce punitive responses on the part of respondents and may, in fact, increase such reactions (see Mehta & Farina, 1997). Attributional accounts of mental disorder, in particular the controllable versus noncontrollable origins of mental illness, therefore remain a puzzling, fascinating, and important research topic.

There may be plausible explanations for the attributional paradox under discussion. First, the symptoms of many forms of mental disturbance are sufficiently threatening to observers that they may precede and override attributional accounts. Thus, the unpredictability and irrationality of such symptoms—along with the symbolic threat they bring to the perceiver's notion of a rational world and to his or her own sense of personal behavioral and emotional control—may engender fear, castigation, and distancing prior to any mitigating effect of a causal explanation, even one that attempts to diminish personal blame and control for the symptom display. The common association, in the public mind, between violence and mental disorder would only fuel such tendencies (Link et al., 1987; Martin et al., 2000).

Second, when respondents are told that mentally disturbed behavior should be attributed to noncontrollable factors that involve aberrant genes or biochemistry, initial resistance would be likely, given the pervasive belief systems in our culture that behavior and emotion are under volitional control. Attempts to foster a medical model of mental illness may thus be viewed as “excuse making” or coddling, engendering reactance. For many, the response might be that medical model ascriptions are part of an overly disease-oriented culture that is attempting to absolve persons with reprehensible behavior from personal control.

Third, however, what if such medical, genetic ascriptions are ultimately accepted, particularly in relation to

deeply disturbing behavior patterns that pose realistic or symbolic threat to perceivers? Again, intriguing evidence suggests that harshly punitive reactions may ensue. This tendency may relate to the linkage of exclusively biomedical/genetic ascriptions to a deep sense of chronicity and hopelessness regarding the sufferer's mental disorder. In addition, if mental disorder is believed to emanate from faulty genes or deficient brain chemistry, essentialist views of its underlying nature as a separately caused, qualitatively distinct entity may be likely to take hold, potentially invoking the forms of tribal stigmas usually reserved for racial or national minorities (Kurzban & Leary, 2001). Paradoxically, then, the medical model attribution may incur an additional source of stigmatization, one that yields exploitation and harsh punishment related to the perception of mental illness as linked with subhumanity.

These ideas are provocative but remain speculative. To gain understanding of their veracity, investigators will need to take social psychological and attributional accounts of mental disorder to more sophisticated levels. That is, we still do not fully know *how* persons in current society view mental disorder and its biomedical attributions. They may, in fact, fundamentally discount reattributions of mental disturbance to biological and genetic causes, continuing to believe that the individual in question really could have controlled his or her behavior and that the biomedical ascription is a kind of modern-day excuse for aberrant behavior. Alternatively, some respondents may undergo a radical attributional shift, coming to the belief that the behaviors in question are the result of a deep, underlying, inborn flaw. Still other respondents may take a perspective that is parallel to demonological accounts of mental disorder in former eras. In such views, a supposedly uncontrollable causal factor, namely, possession by evil spirits or the devil, was actually linked to the belief that the afflicted person was responsible for his or her vulnerability to the possession, perhaps through a moral weakness or lack of faith (Hinshaw, 2004, 2006; Zilboorg, 1941). Reductionistic medical model/genetic views may similarly convey the notion that the individual displaying aberrant behavior is still responsible for being vulnerable to the biological flaw.

In terms of empirical investigations, more open-ended, narrative responses than those encountered in traditional multiple-choice studies of attribution may help to illuminate how members of society comprehend various explanations of mental illness. More complex blends of attribution may be apparent than can be found from forced-choice questions. It may take the exploration of intensive personal narratives, content analyses of advertisements and media

portrayals, and examination of cultural practices and language structures (e.g., jokes, common stories told in various cultures) to uncover the contents of such personal representations of and attributions for mental disorder. It will be particularly important to understand the cultural and linguistic representations of genetic ascriptions for mental disturbance. Indeed, in the coming years, when genetic selection will become far more intentionally directed than has ever been the case in human history, having "deviant genes" may be viewed as an entirely controllable facet of one's makeup. It will be important to know the content of future societal messages regarding individuals who show the behavioral manifestations of a presumed genetic inferiority—and one that could have potentially been controlled or prevented through prenatal selection or genetic manipulation. Overall, it is incumbent on investigators to decode the content of current societal messages regarding the ascriptions for mental disorder and to anticipate the nature of future messages, particularly in relation to genetic loci and their attributional consequences, in terms of their implications for stigma.

Responses of Individuals with Mental Disorder to Stigma

Although research on the responses of the general public to mental disorder has been plentiful for almost 60 years, far less is known about how persons with mental disorder comprehend, internalize, and/or cope with the devaluation and stigmatization they experience. Furthermore, there is an almost complete absence of such information related to children and adolescents with the experience of mental illness. As noted earlier, it was originally assumed that victims of stigmatization would inevitably respond by internalizing the castigation foisted upon them (Allport, 1954). Current social psychological perspectives, however, emphasize that lowered self-esteem and shame are not universal responses to being stigmatized (Crocker et al., 1998). Indeed, many individuals in minority groups display self-esteem and self-concepts fully as positive as those in the majority group. Still, individuals with mental disorders may be particularly likely to evidence shame and reduced self-esteem—related to the very symptoms of many forms of mental illness and to the lack of social cohesion compared to other stigmatized minorities (such as racial groups). Indeed, self-advocacy and political solidarity have been a relatively recent occurrence with respect to mental disorder. For such reasons, internalization of blame may well be expected.

Recall the subdivision of personal coping responses posited by Corrigan and Watson (2002). For one subgroup of persons with mental illness, shame and loss of self-esteem appear to be quite salient, over and above the symptoms of mental disorder. Such individuals display self-stigma. A second group displays active coping responses, including activism; this strategy appears to dissipate shame and self-blame. A third subgroup seems to ignore stigmatizing messages for the most part, going on with their daily lives. Unknown, however, are the proportions of such coping types among individuals with mental disorder, whether these three tendencies constitute the universe of coping responses, the relevant cognitive and emotional processes utilized by individuals in such groups to aid and abet their coping strategies, and the extent to which such a typology applies to youth.

Two additional themes should be investigated. First, research has revealed that some persons in the general population are particularly sensitive to interpersonal rejection and that such *rejection sensitivity* incurs negative consequences for subsequent relationships and the individual's sense of self-worth (Downey & Feldman, 1996). It is quite possible that individual differences in coping with interpersonal rejection may predict adaptive versus maladaptive responses to stigmatization in persons with mental disorder. A degree of imperviousness to rejection could fuel persistence and patience as individuals struggle to complete education, find jobs and housing, and establish meaningful relationships in a stigmatizing and discriminatory society. Others, however, may deeply internalize castigation and attribute it to inner flaws, showing exquisite sensitivity to rejection. The core point is that research on such individual differences in coping styles is almost entirely absent with regard to mental illness.

I do not aim to promote blaming the victim through a call for study of coping responses to stigma. Indeed, it would be a grave mistake to portray the discrimination of mental disorder as a problem related to internal characteristics of the group that is castigated and to blame the consequences of stigmatization on inadequate coping. Still, because systems-level determinants of stigma are not likely to disappear overnight, it is crucial to search for processes that can facilitate adaptive coping.

Second, *stereotype threat* is a phenomenon that has received considerable attention in recent years regarding ethnic and racial minorities. In brief, when a particular societal stereotype is invoked (e.g., "African American individuals are inferior in terms of academic achievement" or "Women are poor at math"), performance on relevant tests suffers accordingly for members of the group in question, once baseline differences in performance are con-

trolled (McKown & Weinstein, 2003; Steele, 1997). Yet, when tests are portrayed in ways that do not invoke the stereotype threat—for example, the test items are stated to be interesting puzzles rather than tests of innate ability—the performance of the stigmatized group does *not* suffer. A salient question is whether stereotype threat exists for at least some individuals with mental disorder. Although this is an interesting possibility, investigators will have to contend with the crucial issue of just what the relevant stereotypes are and in what performance domains they might matter. For example, does the stereotype that persons with mental disorder are unpredictable and unable to hold jobs weaken the performance of at least some persons with mental illness during job interviews? More ominous, does the stereotype that mental disorders are associated with violence (Phelan et al., 2000; Wahl, 1995) serve to instigate a self-fulfilling prophecy, whereby internal mechanisms in the castigated individual as well as expectancies in social partners come to fuel aggressive or acting-out tendencies? These are tantalizing questions that require creative and rigorous research efforts to put them to the empirical test.

In all, the responses of persons with mental disorder to stigma and discrimination is a crucial topic for future research. The most noteworthy social psychological approach, at present, regarding the responses of castigated individuals is identity threat theory, a comprehensive model that integrates multiple levels of social influence and personal appraisal to understanding the potential for stigma to incur negative consequences (Major & O'Brien, 2005). Unfortunately, almost no work related to such models has been applied to the stigmatization of mental disorder.

Although I have argued that self-stigmatization is likely to be particularly salient for individuals with mental disorder, there are few data indeed on which to base such a supposition. Needed are (1) instruments that effectively tap self-blame, shame, and internalization of castigating messages; (2) research paradigms that can separate such features of self-stigmatization from the symptoms of mental disorder; and (3) any viable research on this topic related to children and adolescents. Developing a taxonomy of such coping options would be an important first step. Whether certain individuals with mental disorder are particularly sensitive to rejection is, as yet, unexplored; whether stereotypes related to mental disorder invoke threat and performance decrements on relevant life tasks is unknown.

Families and Mental Health Professionals

Even more than objective types of burden, such as financial costs, finding housing, and providing care, family

members of persons with serious mental illness incur a great deal of subjective burden, a term that entails embarrassment, shame, and a host of related negative emotions related to the difficulties associated with caring for their afflicted relatives (Lefley, 1989, 1992). Beyond descriptive information about such burden, there is an important need to understand the following: Which types of families tend to stay silent about a relative's mental disorder, and which types exhibit openness? Do certain forms of mental illness predict one or the other stance with any specificity? What are the kinds of extrafamilial supports that successful families utilize? At which points in the life cycle of the relative's mental illness do families show the greatest chance of engaging in open dialogue with one another and with relevant professionals? How have changing views of the etiology of mental illness shaped family shame and guilt? Such questions will not be simple to address, but they are crucial for millions of individuals and families worldwide.

I point out, as well, that nearly all of the literature on this topic has emphasized the negative impact of family burden. Hardly investigated, however, is the important question of whether some families' experiences with mental illness in a relative can increase sensitivity, humanity, or ability to cope. In other words, just as individual resilience may emerge from the experience of mental illness, family resilience and strength may be real possibilities as well. But unless family views are solicited and heard in their actual, complex configurations, this possibility cannot be considered to have viability.

The subjective experiences of family members are inextricably linked with professional and scientific views on mental illness. As discussed earlier, some professionals in the field convey stereotypic views of and stigmatizing attitudes toward individuals with mental illness. Yet, nearly all information about attitudes emanates from explicit attitude measures or from selected personal accounts (see Wahl, 1999). Obtaining information on the actual behavioral responses of professionals to persons with mental disorder is a key objective, as are data on the types of *implicit* associations and biases of mental health workers and professionals toward both the constituent behaviors of mental illness and the label itself. Again, research in this area will not be simple to perform, but the dearth of knowledge of this crucial topic needs to be redressed. Finally, it may well be that the majority of current and newly trained mental health professionals hold positive, nonstigmatizing attitudes toward persons with mental disorder—and that such positive outlooks can greatly facilitate strength and coping in individuals and their family

members. Relevant research that could shed light on this topic has simply been lacking.

Developmental Issues Regarding Stigma

Recent research on racial and ethnic bias has taken a decidedly developmental perspective in an attempt to ascertain the ages at which children become aware of prejudice and bias toward people of color (e.g., McKown & Weinstein, 2003). Almost nothing, however, is known about the parallel topic of bias and stigma regarding mental disorder (see Wahl, 2002). In fact, developmental considerations have been sorely lacking from nearly all research on this topic.

Space limitations preclude a full exploration of this critical issue, but I propose several key questions that require elucidation. First, how do stigmatizing attitudes in society (and from mental health professionals) account for the kinds of parental rejection versus acceptance of a diagnosis of mental illness diagnosis in their child? And how does the age of the child relate to such family response? In other words, what are the distinct issues for families of infants/toddlers, preschoolers, grade schoolers, and adolescents in contending with an offspring's mental disorder?

Second, what are children's own reactions, at different ages, to receiving a mental disorder diagnosis? Can such a label be empowering, in that one can begin to attribute negative experiences to an outside entity (an illness) rather than to one's flawed self? Or does the stigma still attached to mental disorder make the receipt of a diagnosis a trigger for even lower self-esteem? Even more basically, how do children of various ages understand what mental illness signifies, both in general and for themselves?

Third, as noted in an earlier section, at what ages and developmental stages do children in the general population begin to understand the concept of behavioral deviance as related to a mental illness? Furthermore, what are the models of mental disorder held by children? Are such perspectives inherently moralistic? Do they pertain to social deviance? Can children understand biological conceptions of mental disturbance? Are youth more or less likely than adults to split their ascriptions to moral versus biomedical causation?

Fourth, at a broader level, how do cultural messages about mental disorder—from the media, from school-based lessons, from peer networks—influence the thoughts and attitudes of children and adolescents in relation to mental disorder? Even children's television cartoons contain frequent, and disparaging, images of mental illness (Wilson et al., 2000), and some of the first words young children use to denigrate disliked peers are slang

terms for mental disorder. A host of research questions emerge from consideration of the ways visual and verbal images regarding mental illness are communicated to and processed by children.

In short, the field is ripe for developmentally oriented investigators to probe both basic and applied questions about the origins and manifestations of stigma in children and adolescents. Such work would enhance knowledge of social cognitive processes across development and facilitate interventions designed to attenuate stigma in its earliest manifestations.

Current Social Issues in Relation to Stigma and Mental Disorder

A number of political and social events and issues in recent years would appear to have important implications for the stigmatization of mental disorder. I list these briefly, in the hope of stimulating relevant inquiries. First, nearly all state budgets across the United States have become awash in red ink during the early years of the twenty-first century. Funds for education, welfare, and mental health are often the first victims of the budget slashing. Will stigmatization of persons with mental disorder increase in such times of economic downturn, as might be predicted from past evidence linking lynchings of African Americans in the South to the price of cotton (Hovland & Sears, 1940; see also Hepworth & West, 1988)? Or will other social and political currents outweigh such economically driven trends? Linking public attitudes temporally with economic and political trends is not a simple undertaking; it typically requires longitudinal data across large time spans, along with a large number of control variables. Yet, investigations of this topic could shed light on important macrolevel variables in relation to stigmatization.

An immediate concern is the potential for parity legislation to be stalled or abandoned because of fears of rising insurance premiums and mental health care costs. Indeed, at the time of the final writing of this chapter (2005), whether more stringent legislation will be passed is an open question. A priority for research on economic-level influences on stigmatization will be to ascertain changes in treatment rates for those with mental disorders as a function of parity laws and other mental health legislation that may become enacted in coming years.

Second, since the terrorist attacks on the United States in September 2001, a surge of ethnic and cultural hatred, often directed against persons of Middle Eastern descent and those of the Islamic faith, has surfaced in this country. It is unknown whether such intolerance has spread, or will spread, to persons with mental disorder. Two reasons make

such an occurrence likely. For one thing, the huge, media-driven stereotype that persons with mental illness are prone to violence would clearly tend to fuel such beliefs. That is, fears of violence have realistically increased in the wake of the terrorist attacks, and those whose behavior patterns are stereotypically linked with danger and aggression—that is, persons with mental disorders—would be expected to increase in salience during such fearful times. For another, recall the fascinating linkage noted between fears of mortality and intolerance of those who are deviant (e.g., Solomon et al., 1991). It has been posited that anxiety over death or annihilation may raise the perceiver's consciousness of the transitory nature of life, spurring stereotyping and castigation of those individuals who threaten community norms as well as personal or societal security and safety. Given the fears raised by the terrorist attack, the blaming of scapegoated individuals, such as those with mental illness, may be expected. Research on such possibilities could reveal systems-level processes, and their interplay with psychological mechanisms, related to prejudice, discrimination, and stigma.

Summary

A host of research questions emerge from analysis of the literature on stigmatization. Indeed, the vast majority of empirical work on stigma pertains to racial and ethnic prejudice, but the applicability of a great deal of such research to mental illness is largely unknown. Important issues pertain to the specification of the dependent variable of stigma (in particular, ensuring that it is more than a few items related to negative attitudes), parallel specification of the independent variable of mental illness (in terms of its inherent variability and specificity), attributional analyses related to personal control versus biogenetic ascriptions and their impact on stigma, the effects of stigma on the self-perceptions of individuals with mental disorders (particularly children and adolescents, on whom relevant research is nearly nonexistent), questions related to parental and family stigma, critical work on developmental factors related to stigmatization, and the impact of current social issues on stigma regarding mental disorder. The importance of the entire topic, and the lack of systematic research to date, make this a potentially exciting and fruitful venture for both basic and applied investigators.

STRATEGIES FOR OVERCOMING STIGMA

Given that stigmatization of mental disorders has been prevalent throughout history, and given the likelihood of

naturally selected roots for at least some aspects of stigmatization, finding strategies to overcome stigma will not be a simple task. Indeed, as noted earlier, increased knowledge of mental illness does not always translate into improved attitudes. Hence, believing that public education about core facts related to mental illness will be sufficient to solve the problem of stigmatization is naïve. A core principle is that stigma processes operate in individual perceivers, whose social cognitions, stereotypes, and implicit biases are relevant; in families, who may internalize messages to conceal and deny mental disorder in a relative; in communities, where ingroup and outgroup processes occur; in cultures, in which stereotyped media portrayals of and other messages about mental illness are promoted; and in broad social policies (e.g., through legislation that does not mandate parity of insurance coverage for mental disorders). Thus, strategies to eliminate stigma that operate at only one level are bound to be shortsighted and ultimately counterproductive (Link & Phelan, 2001). Viable procedures to overcome stigma must occur at multiple, interacting levels. I can address only the most salient procedures in the space remaining (for a recent compendium of multiple views, see Corrigan, 2005).

Social Policy and Culture-Wide Levels

Beginning with broad levels of intervention in the realm of policy, changes in laws can help to limit the discrimination that too often attends mental disorder. For instance, parity of insurance coverage is a major goal; without it, physical illnesses will be treated to a far greater extent than devastating mental illnesses. General health care reform is a priority as well, given the large numbers of uninsured in the United States (note that parity laws pertain only to those individuals and families who already have insurance coverage). Enforcing existing legislation mandating nondiscrimination in employment and housing is also essential. Beyond such enforcement, new initiatives will be required to help promote job skills (and, hence, income levels) in persons with mental disorders.

Regarding children and adolescents, strengthening the provisions of the Individuals with Disabilities Education Act (IDEA) will help to ensure adequate academic attainment for youth with mental disorders. Included here is the guarantee of funding for IDEA; at present, providing assessments and accommodations is mandated under this law, but no federal funds are set aside to assure compliance. An additional suggestion with potentially far-reaching implications is to include behavioral and emotional functioning as part of the medical checkup that children receive each

year from health care providers. Such a preventive approach could bring discussion of children's social and behavioral functioning into the everyday language of doctors and families, helping to deal with the precursors of mental disorders before they become entrenched (Hinshaw, 2006). Although critics attack such screenings as a front for use of psychotropic medications early in a child's life, there is no automatic correspondence between emotional and behavioral checkups and mandatory medication for youngsters at risk. Also important is passage of legislation to end the need for family dissolution or the ceding of child custody to obtain services for troubled youth.

In terms of public media, a far different kind of message about mental illness needs to be transmitted. Information about mental disorder in the print and visual media continues to pertain largely to danger, violence, and utter irrationality, and all too little information about strength, courage, resilience, and positive accomplishments is given. Protest by consumer groups may lead to consciousness raising among writers and producers, although protest movements could lead, in some instances, to a counterproductive rebound of the very messages that are being targeted (Corrigan & Penn, 1999; Wahl, 1995). Furthermore, promotion of poignant disclosures by individuals and families who deal with mental illness on a daily basis provide a different set of images (see Jamison, 1995; Leete, 1992; Styron, 1990; for family accounts, see Hinshaw, 2002; Lachenmeyer, 2000; Neugeboren, 1997). Portrayals of the realities of such conditions as child Autism and ADHD and adolescent mood disorders and eating disorders can set the stage for openness and discussion, rather than silence and shame, about mental illness during childhood and adolescence (Beard & Gillespie, 2002).

Communities

At a community level, the predominant empirically based strategy for overcoming discrimination and stigma has been the "contact hypothesis" (Allport, 1954). From this perspective, changes in attitudes and behaviors are most likely to occur through direct behavioral contact with members of outgroups. In fact, the review of Kolodziej and Johnson (1996) revealed that contact between mental health personnel or students and persons with mental disorder generally facilitated better attitudes.

Overall, it is the *conditions* of contact that are crucial for success. Specifically, contact is most likely to lead to improved attitudes when ingroup and outgroup members have regular, informal contact on an egalitarian basis rather than contrived, artificial contact in which the status differentials are great. Thus, visiting patients in a mental

hospital is not nearly as likely to facilitate enhanced attitudes as is regular interchange in stores, communities, and the workplace. Clearly, improvements in mental health care and enhanced employment opportunities are needed for contact to be more egalitarian than it often is today. Another prerequisite is locating persons with mental disorders in communities, rather than institutions or inner-city board-and-care residences isolated from the mainstream of society. Adequate treatment and social supports are essential aspects of such community intervention. Finally, stigma is likely to diminish when ingroup and outgroup members work toward common, superordinate goals and foster expanded ingroup identity (Gaertner & Dovidio, 2000; Sherif & Sherif, 1953). Advocacy and support groups in which persons with mental disorders, their family members, and the general public interact provide a clear example of such collaboration.

Families

For families, a number of procedures and interventions may serve to lessen subjective burden and bolster coping resources. For example, education about the causes and realities of mental illness, social support from other families grappling with similar issues, and engagement in family-based therapies that provide strategies for dealing with the difficult life issues presented by mental illness are all essential. Furthermore, when a parent has a mental illness, families need to engage children in treatment in such a way as to help them understand that they themselves are not to blame and that their parent is getting help (Beardslee, 2002). Self-help and advocacy groups can reduce isolation, provide needed information, and aid in family coping. In addition, theoretical models in the field that reduce parental blame for the mental illnesses of their offspring, yet simultaneously promote family responsibility for enhancing the course of the disorder, are paramount.

Persons with Mental Illness

Finally, for individuals with mental disorder, including children and adolescents, engagement in empirically supported treatments that can reduce symptoms and facilitate competent academic, social, and vocational performance is an important means of stigma reduction. That is, to the extent that interventions can lessen threatening and maladaptive symptoms, perceivers in society will have less reason to stigmatize those with mental disorders. Note that there are potential dangers in this line of reasoning. Indeed, I do not contend that all responsibility for stigma reduction

should fall on persons with mental illness eliminating all signs of disturbance. This kind of blaming-the-victim mentality is tantamount to positing that the solution for racial prejudice is to have members of minority groups change their skin color. Mental disorder is unlike ethnicity and race in that it is indeed a form of illness: Its signs and symptoms are maladaptive, and treatment may clearly enhance independence and personal growth. Thus, successful treatment is one part of stigma reduction, but clearly not the only component.

Beyond engagement in intervention, finding means of bolstering the coping resources of persons with mental illness is needed. For example, when individuals encounter prejudice, it would seem optimal that they learn to attribute such stigma to the limitations and biases of society rather than to flaws inherent in themselves. Such attributional changes should occur across all family members if the message is to have lasting value. However, given that many forms of mental illness serve to erode self-confidence and a sense of personal value and agency, teaching such coping strategies is a formidable objective.

Summary

The ultimate goal is to find means of promoting change strategies that span individual, family, community, media-related, and social policy levels. Again, there is a danger that ameliorating stigma processes at any one level will leave untouched the pernicious problems at other levels, leading to fragmented, unsustainable change (Link & Phelan, 2001). Yet systematic efforts must begin in earnest (see Hinshaw, 2006, for a more systematic review).

Thus, a great academic, clinical, and policy-related challenge is to apply the basic principles related to stigmatization—across the multiple levels of influence that are operative—to create, implement, and evaluate stigma reduction practices for children, adolescents, adults, and their families and communities. The pervasive shame and silence that surround mental illness, the cyclic nature of reform and retrenchment throughout history, and the deep, automatic, and even naturally selected levels of stigmatizing tendencies toward severe behavioral deviance present major challenges for those who would attempt such intervention. All human societies, however, require diversity, so long as the diverse behavioral manifestations are not threatening to fellow humans. Thus, at the broadest level, successful stigma reduction will require promoting tolerance for a variety of behavioral and emotional styles and allowing all individuals to reach their full potential. Although severe forms of mental disorder may always receive some degree

of social distance and castigation, when compassion and empathy can replace silence, shunning, and blame, and when funding and support for validated treatments allow them to be widely utilized by those who require them, individuals with mental disorder and society at large will benefit. Neither mental illness nor stigma is a static process; understanding the dynamic, developmental nature of both constructs is essential to promote needed change.

940 Subject Index

- Obsessive-compulsive disorder (OCD) (*Continued*)
- obsessional thoughts and compulsive behaviors among older children and adolescents, 412
 - obsessive-compulsive features of early parenting, 412–414
 - diagnostic criteria, 406–407
 - discrete subtypes versus symptom dimensions, 415–416
 - dissociative disorders and, 687
 - early-onset OCD, 416
 - epidemiology, 414
 - etiological perspectives and approaches to treatment, 421–424
 - animal models, 424
 - behavior therapy, 422–423
 - cognitive theories and treatments of OCD, 423
 - descriptive psychiatry and origins of behavior therapy, 421–422
 - learning theory and behavior therapy, 422–423
 - medical/neurobiological etiologies and neurosurgical treatments, 423–424
 - unconscious conflict, the vicissitudes of development, and psychoanalysis, 422
 - future directions, 426–428
 - genetic factors, 418–419
 - hoarding, 416
 - integrative model (melding developmental/evolutionary perspectives), 425–426
 - dynamic interplay of threat and attachment, 426
 - evolutionary perspectives on, 425–426
 - heuristic value, 426–428
 - natural history, 414
 - neurobiology, 419–421
 - neuropsychology, 416–418
 - normal obsessive compulsive behaviors, 421
 - obsessional thoughts, 405
 - obsessive-compulsive personality disorder, 407
 - pregnancy and immediate postpartum period, 419
 - spectrum of disorders, 414–415
 - symptom dimensions, 415–416
 - threat domains, heightened sensitivity, 425
 - tic-related OCD, 416
 - Tourette's syndrome and, 436, 438, 439–442, 448, 455–456, 457, 459
- Occupational therapy, Autism, 342
- Omitted-context-variables problem, 73
- Ontogenic development, psychological, child maltreatment, 134–135, 142–146
- Openness to experience, and parenting, 62
- Opioids, endogenous; Autism and, 337
- Oppositional defiant disorder (ODD):
- child maltreatment and, 162, 164
 - developmental patterns, 505
 - substance abuse and, 606–607
- Organic mental retardation, 240
- PANDAS. *See* Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus (PANDAS)
- Panic disorder, 472, 474–476
- Parent(s)/parenting:
- alcohol use disorder, 632
 - antisocial behavior, 514–519, 525–527
 - anxiety disorders and, 485–486
 - child maltreatment, 141–142
 - competence and, 714
 - conflict (*see* Interparental discord)
 - maltreatment of children (*see* Maltreatment, child)
 - mental retardation:
 - knowledge/perception of, 259–260
 - mother-child interactions, 250–251, 256–257
 - monitoring, 516, 759–760
 - obsessive-compulsive features of early parenting, 412–414
 - psychological symptoms/psychopathology, 52–59, 111–112
 - alcohol use disorders, 55–56
 - antisocial personality disorder, 56–57
 - depression, 53–55
 - Schizophrenia, 57–59
 - social support, 5–9
- Parent-child interaction therapy (PCIT), 179
- Parenting determinants, 38–74
- child characteristics, 42–46
 - defining temperament, 43
 - gender-moderated findings, 45
 - temperament, 43–46
 - genetic influence research, 39–40
 - historical perspectives, etiology of child maltreatment, 40–41 (*see also* Maltreatment, child)
 - marital/partner relationship, 63–70 (*see also* Interparental discord)
 - adolescent years, 68–69
 - affective spillover, 64
 - cause versus correlation, 66
 - domestic violence, 69–70
 - family systems theory, 65–66
 - infant/toddler years, 67–68
 - neighborhood, 70–73
 - preschool/childhood years, 68
 - stress and coping, 64–65
 - withdrawal, 64
 - parental psychopathology, 52–59
 - alcohol use disorders, 55–56
 - antisocial personality disorder, 56–57
 - depression, 53–55
 - Schizophrenia, 57–59
 - parent's developmental history, 46–52
 - breaking the cycle (lawful discontinuity in development), 48–50
 - intergenerational transmission of child maltreatment, 46–50
 - mechanisms of transmission, 47–48
 - “normal” range parenting across generations, 50–52
 - personality, parental, 59–63
 - agreeableness, 61–62
 - conscientiousness, 62
 - extraversion, 61
 - linking processes, 62–63
 - neuroticism, 59–61
 - openness to experience, 62
 - social-contextual model, 41–42
- Parenting/family factors in resilience, 753–761
- autonomy granting, 760
 - biological evidence on benefits of good relationships, 758
 - coexisting warmth and appropriate control, 760–761
 - correcting lack of parental nurturance, 757–759
 - as dependent variable, 762

 - maltreatment effects, 754–755
 - mediators/moderators of community violence effects, 766
 - poverty, 763
 - protective forces, 755–760
 - research needs, 781
- Passive-aggressive personality disorder, childhood maltreatment and, 165
- Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus (PANDAS), 448
- Peer relations:
- antisocial behavior, 520–527
 - child maltreatment and, 156–159
 - delinquency and, 581–582
 - interparental discord and, 112–113
 - natural helpers, 19–20
 - resilience and, 770–772
 - social information processing and, 156–159
 - social support, 14–15, 18
- Peritraumatic Dissociative Experiences Questionnaire (PDEQ), 664
- Personality:
- agreeableness, 61–62
 - antisocial behavior and, 582–583
 - clusters, 161
 - coherence of, 824
 - conscientiousness, 62
 - dysphoric, 161
 - extraversion, 61

- five factor model (FFM), 160
- gregarious, 161
- linking processes, 62–63
- neuroticism, 59–61
- openness to experience, 62
- overcontroller, 161
- parenting and, 48, 59–63
- phenotypic, 824
- reserved, 161
- resilience and, 824–825
- self and, 824
- undercontroller, 161
- Personality disorders:
 - antisocial, 56–57, 573 (*see also* Antisocial personality disorder (ASPD))
 - avoidant, 165
 - borderline, 164–165
 - child maltreatment and, 160–161, 163
 - multiple, 669 (*see also* Dissociation)
 - narcissistic, 165
 - obsessive-compulsive, 407 (*see also* Obsessive-compulsive disorder (OCD))
 - passive-aggressive personality, 165
- Person-based analyses, identifying vulnerability/protective processes, 744–745
- Pervasive developmental disorders:
 - competence and, 715
 - criteria, 319
 - not otherwise specified (PDD-NOS), 319
- Pervasive Developmental Disorders Screening Tests (PDDST), 322
- Pharmacological studies/treatment:
 - anxiety, 478–479
 - Autism, 338
 - psychostimulants, 338
- Pharyngeal infection, 448
- Phenomenological variant of ecological systems theory (PVEST), 776
- Phenylketonuria (PKU), 385, 804–805
- Phobia, social. *See* Anxiety/anxiety disorders; Social phobia
- Phonological awareness, 277
- Phonological processing deficit, 277–300
- Phonological retrieval, 278
- Phonological short-term memory, 279
- Play:
 - Autism and, 328
 - child maltreatment and, 152–153
 - symbolic, 328
- Positive psychology, resilience and, 752
- Positive youth development (PYD) frame, 720–721
- Posterior attention system, 368, 372–373
- Posttraumatic stress disorder (PTSD):
 - anxiety, 471, 472, 474–476
 - biological stress systems, 172, 173
 - child maltreatment, 162, 163, 169–170
 - dissociative disorders and, 664, 672, 676, 680, 687, 688
 - neuroimaging, 169
- Poverty:
 - parenting determinants, 71
 - resilience and, 763
- Prader-Willi syndrome, 235, 246
 - deletion on chromosome 15, 257
 - hyperphagia, 242, 253
 - jigsaw puzzles, 246–247, 253, 257
 - mother-child studies, 251
 - overview table (genetics/prevalence/prominent behavioral features), 246
 - strengths/weaknesses, 246–247
- Predisposition and environment interaction, 804
- Pregnancy and immediate postpartum period, and obsessive-compulsive disorder, 419
- Prejudice, stigma and, 866
- Prenatal/perinatal factors:
 - animal findings, 215
 - biological-conceptual model, 214–215
 - human studies, 215–217
 - Schizophrenia, 546–547
 - stress/anxiety and fetal and child development, 214–217
- Preoccupied style of child emotional security, 102
- Preschool/childhood years. *See also* Child/children:
 - developmental challenges, 115
 - parental marital relationship, 68
 - stigmatization and, 860–861
- Prevention. *See also* Intervention/prevention:
 - interparental discord, 120

- Receptive Language Disorder, 273
- Reciprocal determinism and transaction, stigma and, 863–864
- Rejection sensitivity, stigma and, 872
- Relationships:
 - antisocial behavior, 513, 514
 - situation specificity, 3
 - social support in context of, 2–5
- Religious affiliation, 772
- Representational models, child maltreatment, 153–154
- Residential living programs, adults with Autism, 342
- Resilience, 739–783, 796–832
 - applied developmental science (ADS) and, 752
 - applied science of early childhood intervention, and, 752
 - attachment-based intervention in schools, 768–770
 - autonomy and, 760, 816
 - biology and interdisciplinary work, 748–750
 - as “bouncing back,” 745–746
 - childhood, 739–783
 - behavioral competence, 741
 - historical overview, 740–742
 - community factors:
 - attachment-based intervention in schools, 768–770
 - early intervention and schools, 767–770
 - neighborhoods, 772–773
 - peers and social networks, 770–772
 - religious affiliation, 772
 - research needs, 781
 - violence, 766–767
 - competence and, 696–697, 751
 - concept defined/discussed, 810, 811–814
 - coping and, 816–819, 828
 - definition, 742
 - early experience models and:
 - experience-adaptive or developmental programming, 207
 - life course or cumulative effects models, 208–209
 - sensitive period models, 205

Resilience (*Continued*)

- early intervention and schools, 767–770
 - ego resiliency and, 751
 - empirical research, 819–822
 - future research needs, 761–766, 777–783, 829–832
 - gene-environment interactions, 765, 766
 - hardiness and, 751
 - individual attributes:
 - adult studies, 781
 - altruism, 779
 - ego development, 778
 - emotional intelligence, 777
 - empathy, 779
 - intelligence, 774–775, 777–778
 - malleability in contexts, 773–780
 - personal authenticity, 779–780
 - protective child attributes, 774
 - self-esteem, 779
 - self-regulation, 775–776
 - temperament, 765, 775
 - tendencies to use positive emotions, 780
 - interparental discord and, 117–118
 - later adulthood and old age, 829–832
 - life span perspective on development, 798–810, 829
 - maltreated children and, 165–167, 181
 - model (graphical) of; as constellation of personal/contextual resources, 823
 - as ordinary, 820–822
 - parenting/family factors, 753–761
 - autonomy granting, 760
 - biological evidence on benefits of good relationships, 758
 - coexisting warmth and appropriate control, 760–761
 - correcting lack of parental nurturance, 757–759
 - as dependent variable, 762
 - ethnic minority subgroups, 762–764
 - family routines, 761
 - gene-environment interactions, 766
 - maltreatment effects, 754–755
 - mediators/moderators of community violence effects, 766
 - poverty, 763
 - protective forces; attachment, nurturance, support, 755–759
 - protective parenting; discipline and monitoring, 759–760
 - research needs, 781
 - personality and, 824–825
 - person-centered research approach, 812
 - positive psychology and, 752
 - prevention science and, 751–752
 - protective processes, 743–748
 - reconceptualizing, 780–783
 - related constructs, 750–751
 - related disciplines, 751–753
 - research approaches, 812
 - school-based interventions, 767–770
 - self:
 - content/process, 826–827
 - stabilization, defense, and adaptation of aging self, 822–824
 - self-regulatory processes and, 825–826
 - stigmatization and, 864
 - successful aging, theoretical framework, 827–829
 - underlying processes, 748–750, 761–766
 - as universal, 820–822
 - universal evaluation criteria problem, 814–816
 - variable- or process-centered research approach, 812
 - vulnerability/ protective processes, 743–748
- Response inhibition, 379–380
- Rett's disorder/syndrome:
 - criteria, 318
 - language disorders and, 268
 - stereotypic hand washing/wringing, 242
- Reward response, 380–381
- Rituals, childhood, 407–412
- Routines, family, 761

 - stress-preventive, 9
- Societal issues, stigma and, 874
- Socioeconomic status (SES):
 - Autism spectrum disorders and, 324
 - child maltreatment and, 136, 147, 153
 - social support and, 7
- Somatoform Dissociation Questionnaire (SDQ-20), 664
- Sound processing:
 - auditory rate processing deficit, 280–284
 - Gestalt aspects, 283
 - phonological awareness, 277
 - phonological processing deficit, 277–300
 - phonological retrieval, 278
- Special education services, Autism, 341–342
- Specific emotions theory, 94–95
- Specific phobia, 472
- Speech, perceptual constancy in, 281
- Startle expression, 170–171
- State regulation, attention, 376
- State-space grids, 523
- STEP (School Transition Environment Program), 769
- Stereotype threat, 872
- Stereotypic hand washing/wringing (Rett syndrome), 242
- Stereotypic Movement Disorder (SMD), 439
- Stereotyping and stigma, 842, 866
- Stigma and mental illness, 841–877
 - aesthetics and, 844
 - ambivalence, 846
 - cognitive schema, 846–847
 - concealability and, 844
 - continuities/boundaries between normal/atypical, 863
 - course or longitudinal stability, 844
 - cultural evidence for, 852, 857–860
 - definitions, 842–843, 866–867
 - developmental psychopathology issues related to, 863–864
 - developmental themes, 860–864
 - dimensions of stigmatization, 844–845
 - discriminatory policies, 858–859, 866
 - disruptiveness in social interchange and, 844
 - ecological models, 863
 - economics and, 847–848
 - empirical evidence for, 851–857
 - families/relatives, 855–856
 - general public, 853–855
 - individuals with mental illness, 855
 - mental health professionals, 856–857
 - everyday language, 858
 - evolutionary psychology and, 848–849
 - families and, 855–856, 859–860, 872–873, 876
 - historical perspectives on, 849–852
 - adults with mental disorder, 850–851
 - children with mental illness, 851–852
 - implicit versus explicit expression of prejudice and stigma, 868
 - institutional supports, 847
 - integrative model, 864–866
 - key aspects, 845–848
 - across life span, 860–863
 - adolescence, 861–862
 - adulthood, 862
 - infancy/toddlerhood, 860
 - preschool/school-age children, 860–861
 - motivations, 846–848
 - origin/cause of mental illness, perceived controllability of, 845
 - out-group homogeneity effect, 847
 - personal/family narratives, 859–860
 - pervasiveness and implicit stigma, 845–846
 - prejudice, 866
 - reciprocal determinism and transaction, 863–864
 - research directions, 866–874
 - attributional analysis of stigmatizing responses to mental disorder, 870–871
 - current social issues, 874
 - developmental issues, 873–874
 - issues regarding independent variable of mental disorder, 868–870
 - measurement/appraisal, 866–868
 - responses of families and mental health professionals, 872–873
 - responses of individuals with mental disorder to stigma, 871–872
 - resilience and, 864
 - self-esteem enhancement, 847
 - social cognitions, 846–847
 - social psychology and, 844–848
 - stereotyping and, 842, 866
 - strategies for overcoming, 874–877
 - communities, 875–876
 - families, 876
 - persons with mental illness, 876
 - social policy and culture-wide levels, 875

944 Subject Index

- Stigma and mental illness (*Continued*)
theoretical perspectives on, 843
threat/peril and, 844
- Story stem narratives, 150, 154
- Strange Situation, 147
- Streptosymbolia, 272
- Streptococcus, pediatric autoimmune neuropsychiatric disorders associated with, 448–449
- Stress:
attention and, 367
child maltreatment and, 171–174
depression and, 163–164
mental retardation and, 252
military stress studies, 675–676, 686–687
neuroendocrine functioning, 171–174
parental marital relationship and, 64–65
prenatal (*see* Prenatal/perinatal factors)
Schizophrenia and, 556–558
social support and, 9–11
- Stressful life events (SLEs), 163–164
- Structured Clinical Interview for *DSM-IV* Dissociative Disorders-Revised (SCID-D-R), 665
- Substance abuse, 599–615. *See also* Alcohol use/abuse
adolescence, impact of, 609–610
anxiety disorders and, 606
conduct disorder and, 605, 606
coping abilities and, 610
depression and, 605–606
developmental trajectory models, 611–613
equifinality and multifinality, 614
future directions, 613–614
gender and, 600, 605
intervention research implications, 614–615
magnitude of problem, 600–602
methodological caveats, 606–607
model for initiation of substance use, 611–612
model for progression to continued substance and dependence, 612–613
prevalance table, 623
prevention strategies, 720
protective factors, 610
psychiatric comorbidity, 605
risk factors, 602–610
biological and genetic factors, 607–609
interpersonal factors, 603–604
psychiatric comorbidity, 605
psychobehavioral factors, 604–605
societal and cultural factors, 602–603
risk mechanisms, 613–614
- Suicide, 162
- Switching behaviors, 672
- Symbolic development, 151–154
- Systems theory concept: equifinality, 632
- TEACCH (Treatment and Education of Autistic and Related Communication Handicapped Children) program, Autism, 340–341
- Teacher Report Form (TRF), 174, 388
- Temperament:
anxiety disorders, 485
infants, young children, 160
interparental discord, and child's, 109
resilience and, 765, 775
- Theory of mind (ToM):
Autism, 327–328
child maltreatment, 153
- Thought reform, 668–669
- Threat:
obsessive-compulsive disorder (OCD), heightened sensitivity, 425, 426
stereotype, 872
stigmatization and, 844
- Tic disorders. *See also* Tourette's syndrome:
tic-related OCD, 416
transient tic disorder, 439
- Tool-use paradigm, 149
- Tourette's syndrome, 436–460
adult outcomes, 443
anatomical basis, 450–452
assessing tic severity, 439
cognitive and learning deficits, 454–456
competence and, 715
continuity with normal behaviors, 438–439
co-occurring conditions, 439–442, 449
early intramorbidity course, 442
electrophysiology, electroencephalograms and startle paradigms, 453–454
environmental determinants, 447–449, 457–458
epidemiology, 443–444
etiology, multistrike, 457–458
exposure to stimulants, 449
family studies, 445
future directions, 458–460
genetic vulnerability, 443–447, 457
life events, 449
natural history, 437, 442–443
neurobiological substrate, 449–453
neuropsychology, 454–456
neurotransmitters, 452–453
onset, 442
outcome prediction difficulty, 443
pediatric autoimmune neuropsychiatric disorders associated with streptococcus, 448–449
peer relationships and adaptive functioning, 456–457
perinatal events, 449
phenomenology, 437–438
postpubertal intramorbidity course, 442–443
sex hormones, 447–448
sleep disturbances, 454
startle paradigms, 453–454
- Tourette Syndrome Association International Consortium for Genetics (TSAICG), 418, 447
- Tower of Hanoi (TOH), 417
- Training, social support and, 22
- Trance disorder, dissociative, 668
- Translational research:
anxiety, 489–491
early experience, 226
- Trauma. *See* Dissociation; Posttraumatic stress disorder (PTSD)
- Trisomy 21, 257
